Abstract

In this talk we discuss recent computations of the top quark mass dependence of QCD amplitudes describing Higgs boson production in gluon fusion. We compute terms in the expansion for a large top quark mass, which reduces the Feynman diagrams to products of massless integrals and massive tadpole integrals which contain the top mass dependence. In particular we discuss the real and virtual corrections to double Higgs production at NNLO, and the virtual corrections to single Higgs production at N3LO.

1 Introduction

One of the numerous tasks of the Large Hadron Collider (LHC) is to characterize the structure of the Standard Model's (SM) scalar sector. The parameter λ governs triple and quartic Higgs boson interactions, and is determined in the SM by the mass and vacuum expectation value of the Higgs boson. A direct experimental measurement of λ will help determine if the SM's scalar sector is observed in nature, although such a measurement is very challenging [1, 2].

It is therefore important to have a good theoretical understanding of processes which involve a single Higgs boson and two Higgs bosons. Such processes tend to be dominated by contributions with top quarks propagating in loops, due to the large value of the top quark's Yukawa coupling. Multi-loop amplitudes quickly reach a complexity which cannot currently be handled in an exact manner, so we turn to approximation methods in order to study them. In particular, here, we discuss expansions which consider the top quark mass to be larger than any other scale involved in the problem. The results of such expansions, in addition to providing a good description of amplitudes below the top quark threshold, can be combined with information describing other kinematic regions, to produce approximations which describe amplitudes over a wider kinematic range, see for e.g. Refs. [3–5]. A description of the large- m_t expansion method is given in Section 2 and of some of its applications in Section 3.

2 Large Mass Expansion (LME)

The comparatively large value of the mass of the top quark means that performing an expansion in the limit $m_t \rightarrow \infty$ leads to a sensible approximation of scattering amplitudes, particularly for processes in which contributions due to top quarks dominate. Amplitudes involving Higgs bosons are examples of such processes; the size of the top quark Yukawa coupling means that contributions from other quark flavours are relatively unimportant. The leading term in such an expansion yields the so-called ‘‘Higgs effective field theory’’ (HEFT), in which the top quark is completely integrated out. Dependence on its mass appears only logarithmically in the effective couplings of Higgs bosons and gluons. The goal of the computations discussed in these proceedings is to include *sub-leading* terms of the LME, i.e., terms proportional to powers of $1/m_t^2$.

Such an asymptotic expansion can be performed by the method of ‘‘expansion by sub-graph’’, which is conveniently implemented in the program `exp` [6, 7]. The procedure is to identify all subgraphs of a given Feynman graph which contain the heavy scale (here, m_t) and expand them in their small quantities. The remaining propagators form the ‘‘co-subgraph’’ which does not depend on the heavy scale. For the problem at hand, this means that each Feynman graph is reduced to a sum of products of massless graphs and m_t -dependent vacuum graphs, after the expansion in the limit $m_t \rightarrow \infty$. This procedure is depicted in Fig. 1. For the subgraph identified on the first row, the propagators are expanded as follows:

$$\int \int d^d l_1 d^d l_2 \frac{1}{l_2^2} \frac{1}{(l_2 + q_1)^2} \frac{1}{(l_2 - q_2)^2} \frac{1}{(l_1 + q_1)^2 - m_t^2} \frac{1}{(l_1 - q_2)^2 - m_t^2} \frac{1}{(l_1 - l_2)^2 - m_t^2} \rightarrow \int d^d l_2 \frac{1}{l_2^2} \frac{1}{(l_2 + q_1)^2} \frac{1}{(l_2 - q_2)^2} \int d^d l_1 \left[\frac{1}{(l_1^2 - m_t^2)^3} + \frac{2(q_1 \cdot l_1 - q_2 \cdot l_1 - l_2 \cdot l_1) + l_2 \cdot l_2}{(l_1^2 - m_t^2)^4} + \dots \right], \quad (1)$$

where the ‘‘...’’ represent higher-order terms in the expansion. Within the square brackets, the propagators do not carry external momenta q_1 or q_2 , nor the loop momentum l_2 ; there is only a sum of one-loop vacuum integrals with tensor numerators. Such integrals can be computed by the FORM [8] package MATAD [9], up to three-loop order. For computations which require four-loop vacuum integrals we make use of FIRE [10], which we also use to perform integration-by-parts reduction for the massless co-subgraphs. A more complete description of the computational toolchain is given in the following section.

2.1 Computational Toolchain

For all computations, we begin by generating the necessary Feynman diagrams with `qgraf` [11]. From here, the packages `q2e` and `exp` [6, 7] are used to convert the diagrams into a compatible notation and to identify the relevant subgraphs and co-subgraphs, as described in Section 2. Code is generated for the expansion to be performed by FORM [8], which also computes the colour factors using the COLOR package [12]. Vacuum graphs up to three loops are computed with the MATAD package [9], and four-loop vacuum graphs as well as the massless integrals of the co-subgraphs are reduced to master integrals using FIRE [10]. For the computation of phase-space integrals described in Section 3.1, we use LiteRed [13, 14] and LIMIT [15].

3 Applications

In the following, we summarize some recent works which have used the LME method described above. This includes an NNLO computation of the double-real and real-virtual corrections to

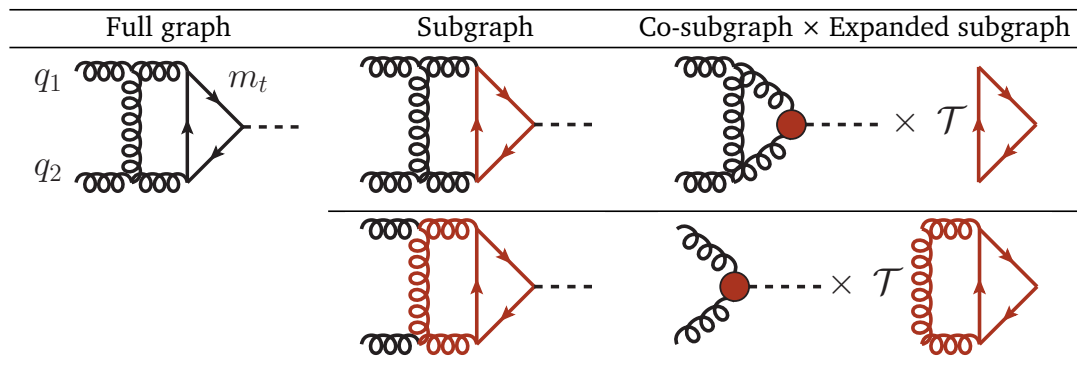

Figure 1: Starting from the full Feynman graph of the first column, we identify the subgraphs which contain m_t -dependent propagators. To perform the LME, the subgraphs are expanded in the large- m_t limit (denoted by the operator \mathcal{T}), leaving only co-subgraphs which are independent of m_t .

Figure 2: Forward-scattering diagrams which contribute to the real-real and real-virtual corrections to NNLO double-Higgs boson production. The blue and green dashed lines denote three- and four-particle cuts through the final state particles.

double-Higgs boson production in gluon fusion [16–18] in Section 3.1, and N3LO computations of the virtual corrections to single-Higgs boson production in gluon fusion [19] in Section 3.2, as well as the decay of a Higgs boson into two photons [20] in Section 3.3.

3.1 NNLO real-radiation corrections to double Higgs boson production

In order to compute real-real and real-virtual corrections we make use of the optical theorem, and compute forward-scattering diagrams which have cuts through the desired final state particles. The real-real corrections correspond to cuts through two Higgs bosons and two additional particles, and the real-virtual corrections to cuts through two Higgs bosons and one additional particle. Examples of such cuts are given in Fig. 2, where the three-particle cuts are shown by blue dashed lines and four-particle cuts by green dashed lines. Some diagrams, such as the first, admit both a three- and four-particle cut. To generate such diagrams an additional step is required to post-process the output of qgraf, which can not itself generate only diagrams containing specified cuts. For this purpose we use the program gen¹.

After large- m_t expansion, the diagrams of Fig. 2 yield the phase-space integrals shown in Fig. 3. These integrals are reduced to a basis of master integrals by LiteRed after the partial fractioning of linearly-dependent propagators by LIMIT. The master integrals are computed in an expansion around $\delta = 1 - 4m_H^2/s \rightarrow 0$, which corresponds to the production threshold of the Higgs boson pair. A deep expansion in δ is obtained efficiently through the use of differential equations, starting from boundary values computed for the leading term in the expansion.

Figure 3: Forward-scattering diagrams which contribute to the real-real and real-virtual corrections to NNLO double-Higgs boson production. The blue and green dashed lines denote three- and four-particle cuts through the final state particles.

Figure 4: NNLO contributions to the total cross sections of the gg and gq channels. The vertical black line shows the threshold at $\sqrt{s} = 2m_t$. The curves show different orders in the large- m_t expansion, denoted by $\rho^n = (m_H^2/m_t^2)^n$.

The total cross section at NNLO is given by

$$\sigma_{ij}^{(2)} = \sigma_{ij,\text{real}}^{(2)} + \sigma_{ij,\text{coll}}^{(2)} + \sigma_{ij,\text{virt}}^{(2)}, \tag{2}$$

where i, j denote the contributing partonic channels, $gg, gq, q\bar{q}, qq, qq'$, including also all additional anti-quark and ghost channels. The collinear counterterms are computed through the convolution of the LO and NLO cross sections with quark or gluon splitting functions. See Section 2.5 of Ref. [18] for a detailed discussion. The virtual corrections have been computed in Ref. [21,22]. After ultra-violet renormalization, the sum of contributions in Eq. (2) produces a finite result.

Plots for successive orders of the large- m_t expansion are shown, for the gg and gq channels, in Fig. 4. Below the top quark threshold the large- m_t expansion converges well, particularly so close to the production threshold. Compared to the leading expansion term (ρ^0), which corresponds to the HEFT result (which has been previously computed in Ref. [23]), including the sub-leading terms typically corrects the NNLO contributions by a factor of two.

3.2 N3LO virtual corrections to single Higgs boson production

For $2 \rightarrow 1$ processes, it is computationally feasible to compute virtual corrections at N3LO, corresponding to four-loop order for loop-induced processes such as single-Higgs boson production in gluon fusion, and Higgs boson decay into two photons (see Section 3.3). Here we compute diagrams such as those shown in Fig. 5. The expansion proceeds in a straightforward manner, as outlined in Section 2. We define the amplitude to be

$$\mathcal{A} = \frac{4\alpha_s(\mu) T_F}{3\pi \nu} \delta^{ab} (q_1 \cdot q_2 g^{\mu\nu} - q_1^\nu q_2^\mu) h(\rho), \tag{3}$$

where q_1, q_2 are the momenta of the incoming gluons, a, b their colour indices, $T_F = 1/2$, and ν is the Higgs vacuum expectation value. After ultra-violet renormalization, the form factor

Figure 5: Virtual corrections contributing to $g g \rightarrow H$ at N3LO.

$h(\rho)$ still contains infra-red poles, however the poles of the rescaled form factor

$$F(\rho) = h(\rho)/h^{(1)}(\rho) = 1 + \mathcal{O}(\alpha_s) \tag{4}$$

are predicted to factorize and given in the literature [24]. We thus consider

$$\log(F) = \log(F)_{\text{poles}} + \log(F)_{\text{finite}} \tag{5}$$

and find that indeed $\log(F)_{\text{poles}}$ is independent of ρ and agrees with Ref. [24], and we may study the numerical impact of the N3LO corrections to $\log(F)_{\text{finite}}$. At a renormalization scale $\mu = m_t$ with an on-shell m_t value of 173 GeV, we find that

$$\begin{aligned} \log(F)_{\text{finite}} = & + a_t [+ (11.07 - 3.06i) + (0.07) + (0.004)] \\ & + a_t^2 [+ (22.59 - 13.24i) + (1.02 - 0.13i) + (0.07 - 0.01i)] \\ & + a_t^3 [- (73.18 + 51.55i) + (7.61 + 0.85i) + (0.70 - 0.14i)], \end{aligned} \tag{6}$$

where the ρ^0 , ρ^1 and ρ^2 expansion terms have been displayed individually in round brackets. We observe that the sub-leading terms in the large- m_t expansion become increasingly important at higher perturbative orders; at N3LO the ρ^1 and ρ^2 terms correct the ρ^0 term by about 10% and 1%, respectively.

3.3 N3LO corrections to Higgs boson decay into photons

From a computational point of view, the decay process $H \rightarrow \gamma\gamma$ is very similar to $g g \rightarrow H$ discussed above in Section 3.2. The Feynman diagrams which contribute are a subset of those of $g g \rightarrow H$, i.e., those for which the external gluons (now photons) couple to a quark line rather than internally propagating gluons. The first diagram of Fig. 5 is such an example. We can therefore apply our existing machinery and reduction to master integrals to this process. We define the partial decay width as

$$\Gamma_{H \rightarrow \gamma\gamma} = \frac{m_H^3}{64\pi} |A(\rho)|, \tag{7}$$

and compute $A(\rho)$ in the large- m_t expansion. Unlike the form factor $h(\rho)$ of $g g \rightarrow H$, $A(\rho)$ is finite after ultra-violet renormalization.

For the top quark mass in the on-shell scheme, Fig. 6 shows the dependence on the renormalization scale of the NLO, NNLO and N3LO corrections, w.r.t. the leading order. At N3LO the curve becomes slightly flatter, but it does not overlap with the NNLO curve.

The N3LO large- m_t result can be combined with the NLO electroweak corrections [25] as well as the NNLO corrections due to bottom and charm quark loops [26],

$$\begin{aligned} \Gamma_{H \rightarrow \gamma\gamma} \times 10^6 \text{GeV}^{-1} = & 9.2581|_{\text{LO}} - 0.1502|_{\text{NLO,EW}} + 0.1569|_{\text{NLO,t}} + 0.0157|_{\text{NLO,bc}} \\ & + 0.0029|_{\text{NNLO,t}} + 0.0036|_{\text{NNLO,bc}} - 0.0031|_{\text{N}^3\text{LO,t}} = 9.2838. \end{aligned} \tag{8}$$

We find that the N3LO top quark corrections are about the same size as each of the NNLO corrections shown in Eq. (8), but come with the opposite sign.

Figure 6: The scale dependence of the large- m_t expansions of the NLO, NNLO and N3LO corrections to $\Gamma_{H \rightarrow \gamma\gamma}$, w.r.t. the exact leading order. m_t is in the on-shell scheme. The vertical black line is at $\mu = m_H$.

4 Conclusion

In these proceedings, we have discussed the large- m_t expansion and its application to several scattering processes. For processes involving Higgs bosons, the size of the top quark Yukawa coupling means that amplitudes with top quarks running in the loops contribute an important part of the total cross sections. The expansion allows the effect of the top quark mass to be well described below the threshold, and including sub-leading terms typically produces large corrections w.r.t. the leading term alone, which corresponds to the commonly-used HEFT.

Such expansions can be performed in a semi-automated and systematic way, allowing us to study multi-loop amplitudes which can not be computed in an exact manner, either analytically or numerically. As discussed in Section 1, these expansions form the input for various approximation methods which combine information from various kinematic regions, in an attempt to describe multi-loop amplitudes over a wider kinematic range than any one expansion alone.
