(Dated: April 21, 2017)

We discuss a class of Dark Matter (DM) models that, although inherently strongly coupled, appear weakly coupled at small-energy and fulfill the WIMP miracle, generating a sizable relic abundance through the standard freeze-out mechanism. Such models are based on approximate global symmetries that forbid relevant interactions; fundamental principles, like unitarity, restrict these symmetries to a small class, in such a way that the leading interactions between DM and the Standard Model are captured by effective operators up to dimension-8. The underlying strong coupling implies that these interactions become much larger at high-energy and represent an interesting novel target for LHC missing-energy searches.

Motivation. Studies of processes with missing energy at the LHC constitute an important part of the Dark Matter (DM) research program, that aims at unraveling possible non-gravitational interactions between the Standard Model (SM) and the dark sector. Information from the LHC would be particularly useful for light DM, $m_{\text{DM}} \lesssim 10$ GeV, below the threshold for direct detection experiments. In this case, the *WIMP miracle* seems to provide a convincing hint that light DM originates from *weakly coupled* dynamics. Indeed, parameterizing the thermally-averaged annihilation cross section as

$$\langle \sigma v_{\text{rel}} \rangle \sim \frac{\alpha_{\text{DM}}^2}{m_{\text{DM}}^2} \quad (1)$$

with m_{DM} , α_{DM} the DM mass and coupling to the Standard Model (SM) fields, we find for the relic density

$$\Omega_{\text{DM}} h^2 \approx \frac{10^{-26} \text{ cm}^3/\text{s}}{\langle \sigma v_{\text{rel}} \rangle} \approx 0.1 \left(\frac{0.1}{\alpha_{\text{DM}}} \right)^2 \left(\frac{m_{\text{DM}}}{10 \text{ GeV}} \right)^2.$$

A weak coupling $\alpha_{\text{DM}} \ll 1$ reproduces the observed value $\Omega_{\text{DM}} h^2 \approx 0.1$ [1].

In this letter we want to explore how solid this indication is and study the viability of light DM associated with a new *strong*, yet perturbative, coupling which we call $g_* \lesssim 4\pi$. The core aspect of our analysis is *approximate symmetries*, which forbid relevant (renormalizable) SM-DM interactions, but allow irrelevant (non-renormalizable) interactions of dimension D . Referring to M as the *physical* scale suppressing the latter, the amplitude for $2 \rightarrow 2$ annihilation, would scale as

$$\alpha_{\text{DM}} \sim \frac{g_*^2}{4\pi} \left(\frac{E}{M} \right)^{D-4}, \quad (2)$$

where E denotes the collision energy. At low energies $E \ll M$, such as those relevant at freeze-out, the interaction of Eq. (2) appears weak, despite their strongly coupled nature at high-energy: this reconciles an underlying

strong coupling with the WIMP miracle. For instance, for $D=6$, considering that in the relevant non-relativistic limit $E \sim m_{\text{DM}}$,

$$\Omega_{\text{DM}} h^2 \approx 0.1 \left(\frac{4\pi}{g_*} \right)^4 \left(\frac{5 \text{ GeV}}{m_{\text{DM}}} \right)^2 \left(\frac{M}{3 \text{ TeV}} \right)^4, \quad (3)$$

showing that even an extremely strongly coupled system $g_* \approx 4\pi$, can reproduce the observed relic abundance, as long as the mediator scale M is in the multi-TeV region.

At high-energy $E \lesssim M$, DM interacts strongly with itself and with the SM, Eq. (2). This is in fact very appealing for the LHC which, operating at high-energy, has direct access to the strongly coupled regime. Moreover, in this regime, the signal from the strongly coupled sector is expected to be strong, and dominate over the LHC irreducible backgrounds (such as $jZ \rightarrow j\nu\nu$). For this reason, because large effects can be obtained even for $E \lesssim M$, DM from a strongly coupled sector provides one of the few examples where the use of a DM Effective Field Theory (EFT) is well motivated even to parametrize LHC DM searches - a topic that has received enormous attention in recent years (see Refs. [2–4] and the literature that followed).

In this note we will use symmetry arguments to discuss all structured scenarios where DM is strongly coupled, but fulfills the WIMP miracle. After identifying the relevant symmetries, we use simple power counting rules to build the EFT describing the physics of these scenarios at collider energies, both in the case where DM is a scalar or a fermion. We will see that, in some cases, the EFT for strongly coupled DM differs substantially from the original DM EFT of Refs. [2–4].

Symmetries. So, what symmetries are compatible with irrelevant operators only? For scalars a well-known example is the shift symmetry associated with Nambu–Goldstone bosons (NGBs) from strong dynamics, like QCD pions. In this case the leading interactions appear at $D=6$ or $D=8$. For Dirac fermions, on the other hand, chiral symmetry and the absence of gauge interactions are enough to guarantee $D \geq 6$. Alternatively, for Majorana

† francesco.riva@cern.ch

‡ alfredo.leonardo.urbano@cern.ch

rana fermions (in analogy with NGBs), non-linearly realized supersymmetry (SUSY) ensures that $D \geq 8$. Indeed the leading interactions of Goldstini from spontaneously broken SUSY only exhibit higher-derivative interactions in the limit where all other SUSY particles are heavy [5].

We will discuss these examples in detail below, but first we want to answer the question of whether, beyond these examples, we can find an infinite set of symmetries such that the low-energy amplitude is suppressed by higher and higher powers of energy, i.e. where $D \geq 10$ constitute the only interactions allowed in the limit of exact symmetry. As a matter of fact the answer is negative. Fundamental principles based on analyticity, unitarity and crossing symmetry of the $2 \rightarrow 2$ amplitude provide strict positivity constraints for some of the coefficients of $D=8$ operators [6]. This implies that generally there is no limit in which a symmetry that protects operators with four fields and $D \geq 10$, forbidding $D \leq 8$, can be considered exact. So the complete set of scenarios with a naturally light strongly coupled DM, that however appears weakly coupled at small E (and therefore fulfills the WIMP miracle) is given by the above examples¹ and is captured by operators of $D \leq 8$.

Scalar Dark Matter. Naturally light scalars originate as pseudo-NGBs of the spontaneously symmetry breaking (SSB) pattern G/H . If the sector responsible for SSB is strong, NGB interactions become strong at high- E . These scenarios are particularly interesting in association with the hierarchy problem [9–15], but also independently from it [16, 17]. Qualitatively different cases of interest can be identified, depending on the particular group structure being considered and the interplay with Higgs physics. First, a light scalar DM can be associated with an abelian $U(1) \rightarrow \mathcal{Z}_2$ breaking pattern, while a light composite Higgs originates from e.g. $G/H = SO(5)/SO(4)$ [18]. Alternatively, the DM originates from a non-abelian, e.g. $SU(2) \rightarrow U(1)$ or larger, symmetry breaking patterns [9, 14–16]. Finally, both the Higgs and DM can arise together from a non-factorizable group G , such as $SO(6)/SO(5)$ [10, 11, 13, 19]. The very power of EFTs is that, at low- E , large groups of theories fall in the same universality classes: in our case the generic EFTs that we will now build to describe the above-mentioned scenarios can be matched to any model with approximate symmetries.

In all these cases, the NGB interactions are described by the CCWZ construction [20]: the light degrees of freedom ϕ^a are contained in the coset representative $U = \exp(i\phi^a t^a/f) \in G/H$ and appear in the La-

grangian only² through the building blocks d_μ^a and ε_μ^A in $U^{-1}\partial_\mu U = id_\mu^a t^a + i\varepsilon_\mu^A T^A$, where $t^a(T^A)$ are the broken (unbroken) generators in G , f is the analog of the pion decay constant and is related to the mass and couplings of resonances from the (strong) sector that induces SSB through the naive dimensional analysis estimate $f = M/g_*$ [21]. Table I shows some specific examples.

G/H	ϕ	d_μ^a	ε_μ^A
$\frac{U(1)}{\mathcal{Z}_2}$	$\phi \in \mathbb{R}$	$\frac{\partial_\mu \phi}{f}$	0
$\frac{SU(2)}{U(1)}$	$\phi \in \mathbb{C}$	$(1 + \frac{ \phi ^2}{f^2} + \dots) \frac{\partial_\mu \phi}{f}$	$\frac{\phi^\dagger \overleftrightarrow{\partial}_\mu \phi}{f^2} + \dots$
$\frac{SO(6)}{SO(5)}$	$H^i, \phi \in \mathbb{R}$	$(1 + \frac{ \phi ^2}{f^2} + \frac{ H ^2}{f^2} + \dots) \frac{\partial_\mu \phi}{f}$	$\frac{H^\dagger \overleftrightarrow{\partial}_\mu H}{f^2} + \dots$

TABLE I. *Building blocks for the effective Lagrangian with different SSB patterns. Dots denote higher order terms in $1/f$.*

Under a transformation $g \in G$, $U \rightarrow gUh(\phi, g)^{-1}$, where $h(\phi, g) \in H$. Then $d_\mu \equiv d_\mu^a t^a$ and $\varepsilon \equiv \varepsilon_\mu^A T^A$ transform under G respectively in the fundamental representation of H and shift as a connection, so that $D_\mu^\varepsilon \equiv \partial_\mu + i\varepsilon_\mu$ is the covariant derivative. With these ingredients, the low energy Lagrangian describing the canonically normalized light scalars only, is simply $\mathcal{L}^{eff} = M^2 f^2 \mathcal{L}(d_\mu^a/fM, D_\mu^\varepsilon/M)$, with the additional requirement of invariance under the unbroken group H : this automatically guarantees also G invariance.

Clearly DM cannot be an exact massless NGB: the global symmetry must be broken explicitly. We keep track of this breaking by weighting interactions that violate the CCWZ construction with m_ϕ^2/M^2 ; an assumption that reflects to good extent the expectations in explicit models (see for instance [10]). We further assume the most favorable case in which, to the extent possible, the SM itself is part of the strong dynamics, as discussed in Ref. [22],³ so that DM-SM interactions do not introduce further symmetry breaking effects (we discuss below cases where only some species take part in the new dynamics). This implies in particular that we assume the new dynamics respects the SM (approximate) symmetries: custodial symmetry, CP, flavor symmetry (broken only by the SM Yukawas [26]) and baryon and lepton numbers. Finally we assume the new dynamics can be faithfully described by a single new scale M and coupling g_* [23]. Compatibly with these assumptions, the most general Lagrangian at the leading $D = 6$ order in

¹ Ref. [7] proposes a somewhat different realization of the same principle, where symmetries imply suppression of the $2 \rightarrow 2$ amplitude in favor of the $3 \rightarrow 2$, which decouples fast as the DM density dilutes. Alternatively, selection rules in the UV could imply p- or d-wave suppressions in the non-relativistic limit, also satisfying our high-energy/strong-coupling, low-energy/weak-coupling dichotomy (yet the implied cross-section suppression is mild $\sim 0.2 \div 0.1$ [8]).

² We will assume that anomalies and the Wess-Zumino-Witten term, that might lead to DM decay in similarity to $\pi \rightarrow \gamma\gamma$ in QCD, vanish.

³ This implies that the Higgs is itself a PNGB [18, 23], SM fermions are partially composite [18, 24], and the transverse polarizations of gauge bosons have strong multipolar interactions [22] – constraints on these possibilities, independent of the new sector couplings to DM, will be studied in [25].

the $1/M$ expansion is,

$$\begin{aligned} {}_6\mathcal{L}_{\text{eff}}^{DM\phi} &= c_\psi^V \frac{g_*^2}{M^2} \phi^\dagger \overleftrightarrow{\partial}_\mu \phi \psi^\dagger \overleftrightarrow{\sigma}^\mu \psi + c_B^{\text{dip}} \frac{g_*}{M^2} \partial_\mu \phi^\dagger \partial_\nu \phi B^{\mu\nu} \\ &+ c_H^S \frac{g_*^2}{M^2} |\partial_\mu \phi|^2 |H|^2 + c_H^\delta \frac{g_*^2 m_{\phi,H}^2}{M^2} |\phi|^2 |H|^2 \\ &+ c_\psi^\delta \frac{g_*^2 y_\psi}{M^2} |\phi|^2 \psi \psi H \end{aligned} \quad (4)$$

where each operator is weighed by the maximum coefficient that we can expect following the power-counting rules associated with the above mentioned-symmetries. The scaling in powers of the coupling g_* can be unambiguously determined from a bottom-up perspective by restoring $\hbar \neq 1$ in the Lagrangian [21, 23, 27]: the coefficient c_i of an operator \mathcal{O}_i with n fields scales as $c_i \sim (\text{coupling})^{n-2}$.

Similarly, at $D=8$, focussing on operators that contribute to $2 \rightarrow 2$ scattering,

$$\begin{aligned} {}_8\mathcal{L}_{\text{eff}}^{DM} &= C_V^S \frac{g_*^2 m_\phi^2}{M^4} |\phi|^2 V_{\mu\nu}^a V^{a\mu\nu} + C_\psi^S \frac{g_*^2 y_\psi}{M^4} |\partial^\mu \phi|^2 \psi \psi H \\ &+ C_V^S \frac{g_*^2}{M^4} |\partial^\mu \phi|^2 V_{\nu\rho}^a V^{a\rho\nu} + C_H^S \frac{g_*^2}{M^4} |\partial^\mu \phi|^2 |D^\nu H|^2 \\ &+ C_V^T \frac{g_*^2}{M^4} \partial^\mu \phi^\dagger \partial^\nu \phi V_{\mu\rho}^a V^{a\rho\nu} + C_H^T \frac{g_*^2}{M^4} \partial^\mu \phi^\dagger \partial^\nu \phi D_{[\mu} H^\dagger D_{\nu]} H \\ &+ C_\psi^T \frac{g_*^2}{M^4} \partial^\mu \phi^\dagger \partial^\nu \phi \psi^\dagger \overleftrightarrow{\sigma}_\mu D_\nu \psi, \end{aligned} \quad (5)$$

with $V_{\mu\nu}^a = B_{\mu\nu}, W_{\mu\nu}^a, G_{\mu\nu}^a$ for $U(1)_Y \times SU(2)_L \times SU(3)_C$ gauge bosons, and ψ, H the SM fermions and Higgs. We use a notation based on left-handed Weyl fermions, which carry additional internal indices to differentiate left-handed ψ and right-handed $(\psi^c)^\dagger$ components of Dirac fermions [8]; the Wilson coefficients c, C , associated to the $D = 6, 8$ Lagrangians respectively, carry these indices, and are expected to be $O(1)$, unless otherwise stated, see table below.

Of course there are more operators that contribute to $2 \rightarrow 2$ scattering, but these can either be eliminated through partial integration, field redefinitions (that eliminate operators proportional to the equations of motion), Bianchi or Fierz identities⁴, or they violate some of the linearly realized symmetries that we assume (CP, custodial). For instance, operators antisymmetric in the Higgs field, such as

$$c_H^{\text{cust}} \frac{g_*^2}{M^2} \phi^\dagger \overleftrightarrow{\partial}_\mu \phi H^\dagger \overleftrightarrow{D}^\mu H \quad (6)$$

transform as **(1,3)** under custodial symmetry $SU(2)_L \times SU(2)_R$: their coefficient is expected to be generated first at loop level by custodial breaking dynamics, involving for instance g' , which satisfies the required transformation rules $c_H^{\text{cust}} \sim g'^2/16\pi^2$. On the other hand at $D=8$,

$$\partial^\mu \phi^\dagger \overleftrightarrow{\partial}_\nu \partial_\mu \phi H^\dagger \overleftrightarrow{D}^\nu H, \quad \partial^\mu \phi^\dagger \overleftrightarrow{\partial}_\nu \partial_\mu \phi \psi^\dagger \overleftrightarrow{\sigma}^\nu \psi, \quad (7)$$

⁴ We eliminate structures involving $\sigma^{\mu\nu}$ in favor of structures that can be generated by tree-level exchange of scalars or vectors.

share the same symmetries (among the linearly and non-linearly realized ones that we have presented⁵) as operators in ${}_6\mathcal{L}_{\text{eff}}^{DM\phi}$ and contribute to the same observables; for this reason their contribution is expected to be always suppressed by $\sim E^2/M^2 \ll 1$ in the amplitude and we neglect them (a similar logic was followed in Ref. [29] to argue that the Peskin-Takeuchi [30] U -parameter can be neglected, since it shares the same symmetries as the T parameter, but is higher-dimension).

Similarly, $m_\phi^2 |\phi|^2 |H|^4$ and $\partial_\mu \phi^\dagger \partial^\mu \phi |H|^4$ give a subleading (by a factor $g_*^2 v^2/M^2 \lesssim 1$) contribution w.r.t. c_H^S and c_H^δ , in processes with 2 longitudinal vectors or Higgses and can only be distinguished in processes with three or more external longitudinal vector bosons/Higgses. Finally, operators of the form $|\phi|^2 \times {}_6\mathcal{L}_{\text{eff}}^{SM}$, where ${}_6\mathcal{L}_{\text{eff}}^{SM}$ is the $D=6$ SM Lagrangian (see Ref. [31]) but also includes total derivatives, are generally further suppressed by m_ϕ^2/M^2 and count as $D=10$ effects in our perspective.

The important novel aspect that is emphasized by our analysis and summarized in the Lagrangians Eqs. (4,5) and table I, is the following. Both the $D=6$ and $D=8$ Lagrangians can be important, as symmetries can suppress the expected leading interactions in favor of higher order ones. Indeed, as table I shows, the structures c_ψ^V vanishes for antisymmetry if DM has a single real degree of freedom (such as for the $U(1)/\mathcal{Z}_2$ and $SO(6)/SO(5)$ cosets), so that in this case the leading DM-fermion interaction is given by the $D=8$ operator C_ψ^T . On the other hand the structures c_ψ^δ and c_H^S are unsuppressed only when the generators associated with ϕ and H do not commute (such as in the $SO(6)/SO(5)$ model [10, 19]), but will be further suppressed by $\sim m_{\phi,H}^2/M^2$ in other cases. In those cases the leading DM-Higgs interactions are the $D=8$ C_H^S and C_H^T . Finally, an important source of suppression is represented by the degree of compositeness of the SM particles - either fermions or (transverse) gauge bosons. The most favorable situation is when the SM particles are fully composite since in this case they feature an unsuppressed g^* coupling to the strong sector. On the contrary, if SM fermions and gauge bosons are elementary degrees of freedom, we expect a suppression in the corresponding couplings, as shown in the first two rows of table II.⁶ In models where the DM dominantly couples to gluons only, the leading effects at high-energy, not suppressed by any small parameters, are the $D=8$ C_V^S and C_V^T . We summarize in table II these and other such situations, where some of the above operators are suppressed by additional small parameters (such as symmetry breaking effects), and become therefore less inter-

⁵ Technically the set of infinite symmetries of the free Lagrangian $\hat{\phi}(p) \rightarrow e^{i\theta(p)} \hat{\phi}(p)$, $\theta(-p) = -\theta(p)$ in momentum space, is broken by the operators of Eq. (7) and those in Eqs. (4,5) to different subgroups, so that a Lagrangian with only the interactions of Eq. (7) is technically natural per se [28]; yet, it is incompatible with the positivity constraints mentioned in the introduction.

⁶ A more realistic situation is when only the right-handed top quark is fully composite [32, 33]; see Ref. [34] for a discussion of DM in this case.

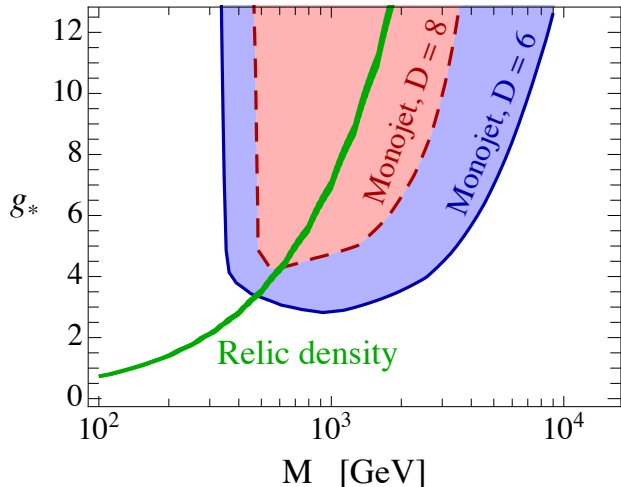

FIG. 1. Constraints on scalar DM with $m_{\text{DM}} = 5$ GeV. Blue region: excluded by consistent LHC constraints on $D=6$ operator c_ψ^V in Eq. (4) (e.g. pseudo-NGB DM from a non-abelian SSB pattern), and comparison with the parameters where the RD is correctly reproduced with the same $D=6$ operator (solid green). Red region: LHC constraints on $D=8$, C_ψ^T in Eq. (5) (e.g. one scalar DM from an abelian SSB).

esting from the point of view of collider searches.

	c_ψ^V	c_B^{dip}	c_H^S	$c_H^\#$	$c_\psi^\#$	$C_V^{S,T}$	C_ψ^T

$SU(2)/U(1)$			×	×	×		
$SO(6)/SO(5)$	×	×					

TABLE II. \times denotes suppression of a given EFT coefficient, according to specific properties of the microscopic dynamics: ψ_{elem} denotes the limit where SM fermions are not composite, V_{elem} denotes instead the familiar case where the transverse polarizations of vectors are elementary (as opposed to strong multipolar interactions [22]).

In Fig. 1 we compare the LHC reach (blue region) in the (g_*, M) -plane with relic density (RD) expectations (green band) for $D = 6$ (e.g. DM as a PNGB of $SU(2)/U(1)$), showing that visible LHC effects are compatible with a non-vanishing RD. Here the LHC constraints have been derived from the data of Ref. [35], imposing an additional cut in the centre-of-mass energy $\hat{s} < M^2$. This cut, and the representation in the (g_*, M) -plane, help us establishing consistency of the EFT assumption [27, 36, 37]. Indeed, as M is lowered within the LHC kinematic region, the constraints rapidly deteriorate, since less and less data remains available: this signals the fact that, in that region, our EFT assumptions are not verified. See a companion paper [8] for more details.

LHC constraints for the examples discussed above,

where $D=8$ represent the leading effect at high- E , are also shown in Fig. 1 with a dashed (red) curve. Notice that here, while the E -growing cross sections implied by our symmetry structure clearly dominate at LHC energies $M \gtrsim E \gg m_{\text{DM}}$, they might be comparable to symmetry breaking m_{DM} -suppressed interaction at low- E , relevant at freeze-out. In other words, the complementarity between different DM experiments is partially lost in this setup – we discuss this issue further in [8].

Fermionic Dark Matter. As mentioned above, if DM is a strongly interacting fermion χ there are two structurally robust situations in which its mass and low-energy interactions might appear small: chiral symmetry for Dirac fermions or non-linearly realized SUSY for Majorana fermions. The first case is familiar: interactions involving the product $\chi_\alpha^\dagger \bar{\sigma}_\mu^{\dot{\alpha}\alpha} \chi_\alpha$ preserve chiral symmetry, while $\chi_\alpha \chi^\alpha$ break it and are expected to be weighed by m_{DM}/M .

In the second case, DM fermions are Goldstini of non-linearly realized SUSY. There are different motivations to discuss this scenario. First of all, a supersymmetric version of the equivalence theorem [38] implies that in the high-energy limit $E \gg m_{3/2}$, the gravitino behaves effectively like a Goldstino (in this case, however, the relation $m_{3/2} \sim F/M_{\text{Pl}}$ implies – for a SUSY breaking sector at $\sqrt{F} \sim \text{TeV}$, necessary to have sizable LHC effects – a very light gravitino). Goldstini are even more interesting in scenarios where $\mathcal{N} = 1$ SUSY is spontaneously broken in $n > 1$ nearly sequestered sectors [39]: in this case $n - 1$ approximate Goldstini appear in the light spectrum and are good DM candidates (their mass being independent from the strength of their interactions). More generally, in an EFT perspective, we can consider the case of approximate $\mathcal{N} \geq 1$ SUSY that, when spontaneously broken, includes light Goldstini in the spectrum [40], and these are good DM candidates.

We work in the simplified limit where all SUSY partners are heavy $m_{\text{susy}} \approx \sqrt{F}$ so that the physics of Goldstini at $E \ll \sqrt{F} \equiv M$ can be described in a formalism that parallels the CCWZ construction [41, 42], adapted to the breaking of spacetime symmetries [43–45]. The coset representative can be written as

$$U = e^{iPx} e^{i\frac{\chi}{2}Q} e^{i\frac{\bar{\chi}}{2}\bar{Q}}, \quad (8)$$

where Q and \bar{Q} are the SUSY generators, χ the Goldstino, and the presence of momenta P is a peculiarity of spontaneously broken space-time symmetries (it can be somehow thought as due to the fact that translations themselves are realized through coordinates shifts, in a way that mimics non-linear realizations [45]). The Maurer-Cartan form is now

$$U^{-1}\partial_\mu U = i\left(\delta_\mu^a + \frac{i}{2}\partial_\mu\chi\sigma^a\chi^\dagger\right)P_a + \frac{i}{2}\partial_\mu\chi Q + \frac{i}{2}\partial_\mu\chi^\dagger\bar{Q}.$$

Here the important building block of the low-energy Lagrangian is $E_\mu^a \equiv \delta_\mu^a + \frac{i}{2}\partial_\mu\chi\sigma^a\chi^\dagger$, which transforms as a vierbein and plays the analogous rôle as ε_μ for

NGBs, rendering a Poincaré-invariant action, written in terms of these building blocks, into one invariant under (non-linear) SUSY. In particular, $\int dx^4 F^2 \det E_\mu^a = i\chi^\dagger \bar{\sigma}^\mu \partial_\mu \chi + \dots$, contains the kinetic term for the canonically normalized Goldstino [46], while interactions with light matter can be described through the vierbein $E_\mu^a(\chi)$ and metric $g_{\mu\nu}(\chi) \equiv E_\mu^a(\chi)E_\nu^a(\chi)$. For our purpose, the important result is that interactions with light fermions ψ , scalars ϕ or gauge field strengths $F_{\mu\nu}$ are captured by the following $D=8$ operators:

$$\begin{aligned} \frac{1}{F^2} \chi^\dagger \bar{\sigma}^\mu \partial_\nu \chi \bar{\psi} \bar{\sigma}_\mu \partial^\nu \psi & \quad \frac{1}{F^2} \chi^\dagger \bar{\sigma}^\mu \chi \partial_\nu \bar{\psi} \bar{\sigma}^\mu \partial^\nu \psi & (9) \\ \frac{i}{F^2} \chi^\dagger \bar{\sigma}^\mu \partial^\rho \chi F_{\mu\nu} F_\rho{}^\nu & \quad \frac{i}{F^2} \chi^\dagger \bar{\sigma}^{\{\nu} \partial_{\mu\}} \chi \partial_\nu H^\dagger \partial^\mu H. \end{aligned}$$

An explicit Goldstino mass can only be associated with explicit SUSY breaking (or departures from exact sequestering in [39]), which will generate operators different from Eq. (9), suppressed by m_{DM}/M . Similarly to the scalar case above, we use this fact and power-counting arguments to write the most general effective Lagrangian weighed by the strongest possible interaction that can be achieved in the scenarios under scrutiny, and postpone more restrictions below.

At leading order in the $1/M$ expansion, the effective Lagrangian for fermionic DM reads

$$\begin{aligned} {}_6\mathcal{L}_{\text{eff}}^{DM} &= c_\psi^V \frac{g_*^2}{M^2} \chi^\dagger \bar{\sigma}^\mu \chi \psi^\dagger \bar{\sigma}_\mu \psi + c_H^S \frac{g_{\text{SM}}^2 m_\chi}{M^2} \chi \chi H^\dagger H \\ &+ c_B^{\text{dip}} \frac{g_* m_\chi}{M^2} \chi \sigma^{\mu\nu} \chi B_{\mu\nu}, \end{aligned} \quad (10)$$

where the coefficient of c_H^S reflects the fact that it does not respect the Higgs NGB symmetry (recall that in order for the Higgs to take part in the strong dynamics and be light, it is expected to arise as a PNGB [23]) and can only arise via effects involving SM symmetry breaking couplings, that we denote generically as g_{SM} . At $D=8$ we find,

$$\begin{aligned} {}_8\mathcal{L}_{\text{eff}}^{DM} &= C_\psi^\# \frac{m_\chi y_\psi g_*^2}{M^4} \chi \chi \psi \psi H + C_\psi^{\#'} \frac{m_\chi y_\psi g_*^2}{M^4} \chi \psi \psi \chi H \\ &+ C_V^\# \frac{g_*^2 m_\chi}{M^4} \chi \chi V_{\mu\nu}^a V^{a\mu\nu} + C_V \frac{g_*^2}{M^4} \chi^\dagger \bar{\sigma}^\mu \partial^\nu \chi V_{\mu\rho}^a V_\nu^{a\rho} \\ &+ C_\psi \frac{g_*^2}{M^4} \chi^\dagger \bar{\sigma}^\mu \partial^\nu \chi \psi^\dagger \bar{\sigma}_\mu D_\nu \psi + C_\psi' \frac{g_*^2}{M^4} \chi^\dagger \bar{\sigma}^\mu \chi D_\nu \psi^\dagger \bar{\sigma}_\mu D_\nu \psi \\ &+ C_H \frac{g_*^2}{M^4} \chi^\dagger \bar{\sigma}^\mu \partial^\nu \chi D_\mu H^\dagger D_\nu H \end{aligned} \quad (11)$$

For generic Wilson coefficients, Eqs. (10,11) represent the most general $D=6,8$ contributions to $2 \rightarrow 2$ on-shell scattering at $D \leq 8$ (for $D=6$ see also [47]). Other structures either violate underlying symmetries or can be eliminated as described in the scalar case above. In particular it can be shown that only three hermitian operators of the form $D^2 \psi^4$ exist at $D=8$ and one, corresponding to the imaginary part of C_ψ in Eq. (11), violates CP and we neglect it. Similarly operators antisymmetric in $H \leftrightarrow H^\dagger$, like $\chi^\dagger \bar{\sigma}^\mu \chi H^\dagger \overleftrightarrow{D}_\mu H$ that plays a rôle

FIG. 2. Same as in Fig. 1, but for fermionic Dirac DM. The region shaded in green corresponds to the observed relic abundance (fermionic DM comes with uncertainty about the chiral structure of the $D = 6$ effective operator considered [8], reflected by the width of the band, contrary to the single line of the scalar case).

in mono-Higgs searches [48], violate custodial symmetry and we neglect them. Moreover, operators of the form $|H|^2 \times {}_6\mathcal{L}^{eff}$ also appear at $D = 8$, but, similarly to the scalar DM case, they are expected to be small (if the Higgs is also a PNGB) and moreover they only affect processes with additional h .

So, for composite Dirac fermions, only the $D = 6$ c_ψ^V is important (also, for light DM c_B^{dip} and c_H^S are constrained by constraints from Z and h decays) in Fig. 2 we show that the LHC is here providing the most important piece of information, accessing the region in parameter space that reproduces the observed RD.⁷ Nevertheless, if χ is a Goldstino, then the $D = 6$ Lagrangian vanishes in the limit of exact SUSY, and the first strong interactions appear at $D = 8$. In this case only C_V and $C_\psi^{(l)}$ are important for mono-jet analyses. This is an example (similar to the $U(1)/\mathbb{Z}_2$ PNGB) where approximate symmetries, that were invoked to hide strong coupling at small energy, go as far as suppressing the first order $1/M^2$ terms but allow the $1/M^4$ ones. Even in this case the LHC contains important information (dashed line of Fig. 2).

Outlook. In Summary, we have discussed natural situations in which light DM originates from a strongly-coupled sector but its interactions are small at low-energies because of approximate symmetries, that forbid relevant interactions and allow only irrelevant (higher-derivative) ones. Prime principles dictate that such symmetries are consistent only with $D=6$ and $D=8$ opera-

⁷ In addition to our E -scaling, renormalization group effect can play a rôle in the precise comparison between LHC and RD probes (see e.g. [49]).

tors for $2 \rightarrow 2$ scattering. In this article we have identified generic effective Lagrangians at these orders and introduced a power-counting that captures the most well-motivated scenarios that can imply large effects in irrelevant interactions: scalar DM as a PNGB, or fermion DM as a strongly coupled fermion or Goldstino.

These provide a class of models in which the LHC high- E reach plays an important rôle with respect to other types of experiments (such as RD indications and direct detection) and contains genuinely complementary information. Moreover, in these scenarios the DM EFT is not only consistent with LHC analysis (due to the underlying strong coupling, as shown in Figs. 1 and 2), but also necessary, as the underlying dynamics is uncalculable. Our characterization provides a well-motivated context to model missing transverse-energy distributions

at the LHC, in mono-jet, mono- W, Z, γ or mono-Higgs searches, with a handful of relevant parameters and yet a clear and consistent microscopic perspective. To the question of what we have learned from LHC DM searches, these models provide one answer.
