1

2 Abstract

3 The part-per-million measurement of the positive muon lifetime and determination of
4 the Fermi constant by the MuLan experiment at the Paul Scherrer Institute is reviewed.
5 The experiment used an innovative, time-structured, surface muon beam and a near- 4π ,
6 finely-segmented, plastic scintillator positron detector. Two in-vacuum muon stopping
7 targets were used: a ferromagnetic foil with a large internal magnetic field, and a quartz
8 crystal in a moderate external magnetic field. The experiment acquired a dataset of
9 1.6×10^{12} positive muon decays and obtained a muon lifetime $\tau_\mu = 2196980.3(2.2)$ ps
10 (1.0 ppm) and Fermi constant $G_F = 1.1663787(6) \times 10^{-5} \text{ GeV}^{-2}$ (0.5 ppm). The thirty-fold
11 improvement in τ_μ has proven valuable for precision measurements in nuclear muon
12 capture and the commensurate improvement in G_F has proven valuable for precision
13 tests of the standard model.

14 16.1 Introduction

15 The electromagnetic (α_e), strong (α_s), gravitational (G) and weak (G_F) couplings are the
16 “calibration constants” of nature [1]. Their magnitudes haven’t been determined by theory
17 but rather are obtained from measurement. Collectively, they determine the dynamics and
18 bindings of microscopic and macroscopic matter and the character of the universe.

19 The fine-structure constant α_e governs the scale of atomic energy levels and the rates of all
20 electromagnetic processes. It is known to the astonishing precision of 0.15 parts per billion.

21 The energy-scale-dependent effective coupling α_s governs the binding of protons and neu-
22 trons to form nuclei and the production of chemical elements in stars. It also controls the
23 emergence of the two faces of the strong interaction: quark confinement at large distances
24 and asymptotic freedom at short distances.

25 Despite the omnipresence of the gravitational force and its implications for the structure of
26 the universe, the precision determination of the gravitational constant G has been deceptively
27 difficult. Since its original measurement by Cavendish, the surprising inconsistencies between
28 modern methods have meant little overall improvement in our knowledge of this constant [2].

29 Finally, the weak interaction governs the thermonuclear reactions in the sun that are ul-
30 timately responsible for light, energy and life. The understanding of weak interactions en-
31 ables the computation of phenomena from cosmology and astrophysics to nuclear and particle
32 physics, including exacting tests of electroweak theory. Fermi described the weak processes
33 by a simple four-fermion contact interaction with the coupling strength that became known as

34 G_F . This constant and the current-current weak interaction description have survived many
 35 decades as a very convenient, low-energy, effective theory. Of course, our modern understand-
 36 ing of weak interactions has evolved to incorporate such features as parity violating $V - A$ cur-
 37 rents and heavy W, Z gauge bosons, in a unified electroweak theory described by two gauge
 38 couplings and the Higgs energy density. The Fermi constant G_F , together with measurements
 39 of α_e and M_Z , provide by far the best determinations of the gauge couplings and Higgs energy
 40 density.

41 Since its discovery in 1933, the muon, a heavy sibling of ordinary electrons, has played
 42 a significant role in subatomic physics. Muons are undoubtedly the best tool for the precise
 43 determination of the Fermi constant and, uniquely from the considerations above, provide
 44 by far the most precise measure of the weak coupling. From the theoretical perspective, the
 45 purely-leptonic muon decay is well suited to precision calculations within the Fermi theory,
 46 and from the experimental perspective, its microsecond-scale lifetime is well suited to modern
 47 techniques for time measurements. Because the best method to determine G_F is from the
 48 muon lifetime, it is appropriate to recognize that what is measured is G_μ , the muon constant
 49 in weak decay. The assumption of lepton universality allows the relation $G_F \equiv G_\mu$, which we
 50 assume here, but can and should be challenged by other weak interaction processes.

51 An important breakthrough for determining G_F was work by van Ritbergen and Stuart [3]
 52 and Pak and Czarnecki [4]. Using Fermi theory with 2-loop QED corrections, these authors
 53 reduced the theoretical uncertainty in the relation between the muon lifetime and the Fermi
 54 constant from 15 parts-per-million to 150 parts-per-billion. Their work thus opened the door
 55 for the MuLan experiment at PSI [5, 6], a part-per-million measurement of the muon lifetime
 56 τ_μ and determination of the Fermi constant G_F – a thirty-fold improvement over earlier mea-
 57 surements.

58 16.2 Experimental setup

59 The principle of the MuLan measurement of the muon lifetime is straightforward.

60 First, prepare a small “source” of positive muons. Next, measure the times of decay
 61 positrons. Finally, construct the exponential decay curve and extract the positive muon life-
 62 time. In practice we repeated the sequence of source preparation and positron measurement
 63 at approximately 30 KHz over a period of roughly 20 weeks in two running periods.

64 The experiment used longitudinally polarized, 29 MeV/c, positive muons from the $\pi E3$
 65 secondary beamline at the PSI proton cyclotron. Incoming muons were stopped in solid tar-
 66 gets and outgoing positrons were detected in a near- 4π , finely segmented, fast-timing, plastic
 67 scintillator positron detector. The analog signals from individual scintillators were recorded by
 68 450 MSPS (mega samples per second) waveform digitizers and accumulated by a high-speed
 69 data acquisition system.

70 One innovative feature of the system was the imposition of time structure in the $\pi E3$
 71 beamline. The experiment operated in repeating cycles of beam-on accumulation periods, in
 72 which surface muons were accumulated in the stopping target, and beam-off measurement
 73 periods, in which decay positrons were detected in the MuLan detector. The time structure
 74 avoided the need to associate the decay positrons with parent muons – a limiting factor of
 75 earlier experiments using continuous beams.

76 The specific time structure comprised a 5 μs -long beam-on accumulation period (T_A), and
 77 a 22 μs -long beam-off measurement period (T_M). The time structure was imposed on the
 78 $\pi E3$ beam using a custom-built, fast-switching, 25 kV electrostatic kicker. When the kicker
 79 was de-energized, the muons were transported to the Target; when the kicker was energized,
 80 the muons were deflected into a collimator. A sample time distribution of incoming muons
 81 and outgoing positrons that illustrates the accumulation and measurement periods is shown
 82 in Figure 16.1.

Figure 16.1: Plot of the time dependence of the muon arrival rate (upper panel) and decay positron counts (lower panel) that was imposed by the electrostatic kicker. The durations of the beam-on accumulation period and beam-off measurement period were $T_A = 5 \mu\text{s}$ and $T_M = 22 \mu\text{s}$, respectively. Figure courtesy of the MuLan collaboration.

83 Other innovative features of the experiment were the use of in-vacuum stopping targets
 84 and near- 4π positron detection. A consequence of parity violation in weak interactions is
 85 that the emitted positrons in muon decay are asymmetrically distributed about the muon spin
 86 direction. This poses a problem as spin precession and spin relaxation of stopped muons could
 87 distort the pure exponential time distribution of the decay positrons and bias the extraction of
 88 τ_μ .

89 A fully 4π , perfectly isotropic, positron detector would negate this issue of precession
 90 and relaxation by detecting positrons with identical probability in all directions. The MuLan
 91 combination of an in-vacuum, detector-centered target for incoming muons and near- 4π , near-
 92 isotropic, detector for outgoing positrons, was an important part of the experimental strategy
 93 for minimizing such spin precession and relaxation effects.

94 In addition, the experiment deployed two different combinations of stopping target materi-
 95 als and transverse magnetic fields in order to further reduce the spin precession and relaxation
 96 effects. One setup involved a magnetized Fe-Cr-Co foil (Arnokrome-III) with a ~ 4 kG inter-
 97 nal B -field. Another setup involved a quartz crystal disk (SiO_2) in a 130 G external B -field.
 98 In the ferromagnetic target, where muons reside as diamagnetic ions, the μ^+ precession fre-
 99 quency was about 50 MHz. In the quartz target the primary muonium (μ^+e^-) population has
 100 a 180 MHz precession frequency and the secondary muon (μ^+) population has a 1.8 MHz
 101 precession frequency. In both strategies, spin dephasing during muon accumulation yielded a
 102 roughly 1000-fold reduction in the ensemble-averaged μ^+ polarization at the beginning of the
 103 measurement period.

Figure 16.2: A cutaway view of the MuLan experimental setup showing the (1) vacuum beamline, (2) in-vacuum stopping target, (3) Halbach arrangement permanent magnet, (4) soccer ball geometry scintillator array, and (5) beam monitor. We used the Halbach magnet for the external magnetic field in the quartz target data-taking. Figure courtesy of the MuLan collaboration.

104 The positron detector was constructed of 170 triangle-shaped, plastic scintillator pairs ar-
 105 ranged in a soccer ball geometry (Figure 16.2). Each pair comprised an inner and outer scin-
 106 tillator tile. The pairs were grouped into ten pentagonal enclosures containing five tile-pairs
 107 and twenty hexagonal enclosures containing six tile-pairs, which together formed the soccer
 108 ball geometry. The segmentation was important in reducing positron pile-up in individual de-
 109 tector elements. The symmetric arrangement of detector elements was important in reducing
 110 the effects of muon spin rotation / relaxation.

111 16.3 Data analysis

112 A total of 1.1×10^{12} decays from positive muon stops in Arnokrome-III and 5.4×10^{11} decays
 113 from positive muon stops in quartz were collected. Other datasets with different orientations
 114 of the magnetic field and different centering of the muon stopping distribution were collected
 115 in order to study the systematic errors associated with spin precession and relaxation.

116 The time and amplitude of individual pulses were determined from least square fits to dig-
 117 itized waveform templates. The procedure fit a higher-resolution template waveform (0.22 ns
 118 sampling-interval) to the lower-resolution individual waveforms (2.2 ns sampling-interval).
 119 The higher-resolution templates were constructed by combining a large sample of 2.2 ns
 120 sampling-interval, single positron, digitized waveforms. The fitting procedure would add /
 121 remove pulses to obtain the best χ^2 .

122 Positrons were defined as inner-outer tile-pair coincidences. In identifying the coinci-
 123 dences, cuts were applied to define an unambiguous amplitude threshold A_{thr} for detector
 124 hits and to define an unambiguous artificial deadtime (ADT) between detector pulses. Hits
 125 that survived these cuts were sorted into time distributions of inner singles, outer singles and
 126 inner-outer coincidences. The construction of coincidence histograms with different thresh-
 127 olds and deadtimes was important for studying the distortions that arise from pulse pileup
 128 and gain changes. The typical rates were 40 stopped muons per accumulation period and 15

129 detected positrons per measurement period. The nominal 13.3 ns ADT yielded a pileup dis-
 130 tortion of roughly 10^{-3} at the start of the measurement period and roughly 10^{-7} at the end of
 131 the measurement period.

132 A hit is lost if it occurs in the artificial deadtime of an earlier hit. Our procedure for cor-
 133 recting for pileup took advantage of the time structure of the incident beam. The pileup losses
 134 were statistically recovered by replacing the lost hits in each measurement period with mea-
 135 sured hits at equivalent times in neighboring measurement periods. For example, to correct for
 136 leading-order pileup, if a hit is observed at time t_i in fill j (the “trigger” hit), a hit is searched
 137 for within the interval $t_i \rightarrow t_i + \text{ADT}$ in fill $j + 1$ (the “shadow” hit). Adding the resulting
 138 histogram of shadow hit times to the original histogram of trigger hit times thus statistically
 139 recovers the lost hits (similar shadow methods were employed for handling the higher-order
 140 pileup).

141 As mentioned, only hits with amplitudes exceeding the threshold A_{thr} were used. Conse-
 142 quently, if the detector gain changes over the measurement period, then the time histogram
 143 will be distorted by either additional hits climbing above A_{thr} or additional hits falling below
 144 A_{thr} cut. We corrected for gain changes versus measurement time by monitoring changes in
 145 the positron minimally ionizing particle (MIP) peak amplitude over the measurement period.

146 A simple procedure was used to extract the lifetime τ_μ from the Arnokrome-III target. The
 147 summed tile-pair time histogram of coincidence hits was fit to $Ne^{-t/\tau_\mu} + C$. The approach relied
 148 on sufficient cancellation of Arnokrome-III precession and relaxation effects by combination
 149 of the spin dephasing and the opposite-pair detector geometry.

150 A more complicated procedure was needed to extract the lifetime τ_μ from the quartz target.
 151 First, 170 geometry-dependent effective lifetimes were extracted for each tile-pair from fits to

152

$$N(t) = Ne^{-t/\tau_{\text{eff}}}[1 + f(t)] + C, \quad (16.1)$$

153 where $f(t)$ accounts for time-dependent effects of transverse-field (TF) spin precession and
 154 relaxation. Then, the true positive muon lifetime τ_μ was extracted by fitting the effective
 155 lifetimes, τ_{eff} , to

$$\tau_{\text{eff}}(\theta_B, \phi_B) = \tau_\mu[1 + \delta(\theta_B, \phi_B)], \quad (16.2)$$

156 where $\delta(\theta_B, \phi_B)$ accounts for geometry-dependent effects of longitudinal-field (LF) spin relax-
 157 ation. Together the two steps were sufficient to handle the effects of precession and relaxation
 158 in quartz.

159 16.4 Results

160 The individual results from the Arnokrome-III dataset and the quartz dataset, and the weighted
 161 average are given in Table 16.1.

Target material	Positive muon lifetime (ps)
Arnokrome-III	$2\,196\,979.9 \pm 2.5(\text{stat}) \pm 0.9(\text{syst})$
Quartz	$2\,196\,981.2 \pm 3.7(\text{stat}) \pm 0.9(\text{syst})$
Weighted average	$2\,196\,980.3 \pm 2.1(\text{stat}) \pm 0.7(\text{syst})$

Table 16.1: Muon lifetime results from the Arnokrome-III dataset, quartz dataset, and their weighted average.

162 The weighted average corresponds to an overall uncertainty in the positive muon lifetime
 163 of 2.2 ps, or 1.0 ppm. The largest contributions to the systematic uncertainties are associated
 164 with the aforementioned pulse pileup, gain changes, and muon precession and relaxation

165 effects, as well as the knowledge of the time independence of the beam extinction during the
166 measurement period. The final result for τ_μ is in agreement with the earlier work of Giovanetti
167 *et al.* [7], Balandin *et al.* [8] and Bardin *et al.* [9].

168 We note the precision determination of τ_μ is important to work on nuclear muon capture.
169 The MuCap experiment [10] at PSI determined the μp singlet capture rate from the small dif-
170 ference between the positive muon lifetime and the muonic hydrogen atom lifetime. Similarly,
171 the MuSun experiment [11] at PSI will determine the μd doublet capture rate from the small
172 difference between the positive muon lifetime and the muonic deuterium atom lifetime. These
173 two experiments are described in Section 17 [12] and Section 18 [13], respectively.

174 The Fermi constant G_F was extracted using the relation obtained by van Ritbergen and
175 Stuart (vRS) [3] and yields $G_F(\text{MuLan}) = 1.166\,378\,7(6) \times 10^{-5} \text{GeV}^{-2}(0.5 \text{ ppm})$ – a thirty-
176 fold improvement over the earlier 1998 Particle Data Group [14] value that pre-dated the
177 vRS theoretical work and MuLan experimental work. The 0.5 ppm error is dominated by the
178 1.0 ppm uncertainty of the lifetime measurement, with contributions of 0.08 ppm from the
179 muon mass measurement and 0.15 ppm from the theoretical corrections.

180 Together, the fine structure constant α , Fermi coupling constant G_F , and Z boson mass M_Z ,
181 fix the electroweak parameters of the standard model. The thirty-fold improvement in the
182 determination of the Fermi constant G_F , together with other improvements in determinations
183 of α and M_Z , have allowed for improved tests of the standard model and improved searches
184 for new phenomena.

185 We wish to thank our collaborators in the MuLan experiment and Paul Scherrer Institute
186 for their exceptional organizational and technical support. We also wish to thank M. Barnes
187 and G. Wait from TRIUMF for their development of the electrostatic kicker, Bill Marciano for
188 advocating and promoting the experiment, and the U.S. National Science Foundation (NSF
189 1807266) and U.S. Department of Energy (DOE DE-FG02-97ER41020) for their financial sup-
190 port.
