Review of Particle Physics at PSI
doi:[10.21468/SciPostPhysProc.2](https://doi.org/10.21468/SciPostPhysProc.2)

Abstract

The nEDM apparatus at PSI has been used to search for different dark matter signatures utilizing its high sensitivity to shifts in the neutron precession frequency and its well-controlled low magnetic field at the μT level. Such a shift could be interpreted as a consequence of a short-range spin-dependent interaction that could possibly be mediated by axions or axion-like particles, or as an axion-induced oscillating electric dipole moment of the neutron. Another search, based on so-called UCN disappearance measurements, targeted previously reported signals of neutron to mirror-neutron oscillations. These dark matter searches confirmed and improved previous results, as detailed in this review.

28.1 Introduction

Apart from searching for the electric dipole moment of the neutron, the nEDM apparatus at PSI (Section 18 [1]) is also an excellent tool to search for signatures of dark matter particles. The first potential signature studied was a high precision measurement of the shift in the ratio of the spin-precession frequencies of ultracold neutrons (UCN) and ^{199}Hg atoms. This shift can be interpreted as originated from a possible short-range spin-dependent neutron–nucleon interaction [2]. A second search focused on ultra-low-mass axionlike dark matter. The aforementioned ratio was measured and analyzed as an axion-induced oscillating electric dipole moment of the neutron and an axion-wind spin-precession effect [3]. UCN disappearance experiments were conducted with this apparatus [4] to search for dark matter signatures. It was proposed in the fifties that there could be a mirror copy of the Standard Model (SM) particles, restoring parity conservation in the weak interaction on the global level. Oscillations between a neutral SM particle, such as the neutron, and its mirror counterpart could help explain various issues in physics, including dark matter. The neutron electric dipole moment collaboration at PSI conducted an experiment to search for anomalous signals reported before.

Below we summarize the results of our experiments aiming at identifying dark matter signatures with the nEDM apparatus at PSI. A comparison to previous constraints on model parameters will be given.

28.2 Search for axion-like particles

The most elegant solution to the strong CP problem is to introduce a global chiral $U(1)$ symmetry, usually named $U(1)_{PQ}$ after the two physicists who first proposed it, R. D. Peccei and

41 H. R. Quinn [5] in 1977. $U(1)_{PQ}$ is spontaneously broken at some energy scale f_a producing
 42 a pseudo-Nambu-Goldstone boson of the global $U(1)_{PQ}$ symmetry: the axion, as proposed by
 43 S. Weinberg and F. Wilczek [6].

44 One defining feature of the axion is the inverse proportionality of the mass m_a to the
 45 $U(1)_{PQ}$ symmetry breaking scale f_a . Therefore, one needs only one parameter to describe the
 46 axion's properties. In reference [7], the proportionality factor is computed from first principles
 47 and using lattice calculations giving

$$m_a = 5.70(6)(4) \mu\text{eV} \left(\frac{10^{12} \text{ GeV}}{f_a} \right) \quad (28.1)$$

48 The axion is a well-motivated dark matter candidate, as it would solve the strong CP prob-
 49 lem and possibly explain the observed abundance (or a fraction of it) of the dark matter. How-
 50 ever, observing the axion in the mass range where it would explain the dark matter abundance,
 51 requires probing a very weak coupling.

52 Experimentally, searching for an "axion" outside the window defined by (28.1) is referred
 53 to as searching for axionlike particles.

54 An important feature of the nEDM spectrometer [?] is the mercury co-magnetometer. The
 55 search for the neutron electric dipole moment employs the ratio \mathcal{R} of the neutron precession
 56 frequency (f_n) to the mercury one (f_{Hg}) using the fact that this ratio is, to first order, free from
 57 magnetic field fluctuations. Similarly, this ratio can be used to search for exotic couplings
 58 forming a class of experiment called clock comparison. In the following, we focus on how to
 59 search for axion-like particles with advanced clock comparison experiments using the ratio \mathcal{R}
 60 according to equation:

$$\mathcal{R} \equiv \frac{f_n}{f_{\text{Hg}}} = \frac{\gamma_n}{\gamma_{\text{Hg}}} \left(1 + \frac{\vec{b} \cdot \vec{B}}{B^2} \pm \left(d_n - \frac{\gamma_n}{\gamma_{\text{Hg}}} d_{\text{Hg}} \right) \frac{2E}{hf_{\text{Hg}}} \right) \quad (28.2)$$

61 In this expression \vec{B} (\vec{E}) is the applied magnetic (electric) field. These fields are parallel to
 62 each other. This ratio is sensitive to an EDM-like coupling (for the neutrons (d_n) or for the mer-
 63 cury atoms (d_{Hg})) and to any coupling generating a pseudo-magnetic field acting differently
 64 on neutrons and mercury atoms so that its effective strength \vec{b} is not null.

65 Some models predict that low mass axions ($m_a \leq 0.1 \text{ eV}/c^2$) [8] could have been produced
 66 in the early universe and would form now a coherently oscillating classical field of amplitude
 67 a depending only on the axion's mass m_a [9]

$$a(t) = a_0 \cos\left(\frac{m_a c^2}{\hbar} t\right) \quad (28.3)$$

68 The same models predict an oscillation of the ratio \mathcal{R} induced by the coupling [3]

$$\mathcal{L} = \frac{C_G}{f_a} \frac{\alpha_S}{8\pi} G_{b\mu\nu} \tilde{G}^{b\mu\nu} - \frac{C_N}{2f_a} \partial_\mu a \bar{N} \gamma^\mu \gamma^5 N \quad (28.4)$$

69 where b is the color index while C_G , the axion-gluon coupling, and C_N , the axion-nucleon
 70 coupling, are model dependent dimensionless parameters. The first term is the axion-gluon
 71 coupling. It induces an oscillation of the neutron EDM through the same mechanism as the
 72 QCD theta term. The second term is the axion-nucleon coupling. It induces an E-independent
 73 frequency modulation of the ratio \mathcal{R} . In both cases, the frequency of the oscillation depends
 74 on the (unknown) mass of the axion, see (28.3). The limits obtained at PSI on the couplings
 75 C_G and C_N for different axion mass are shown in Figure 28.1a and Figure 28.1b respectively.

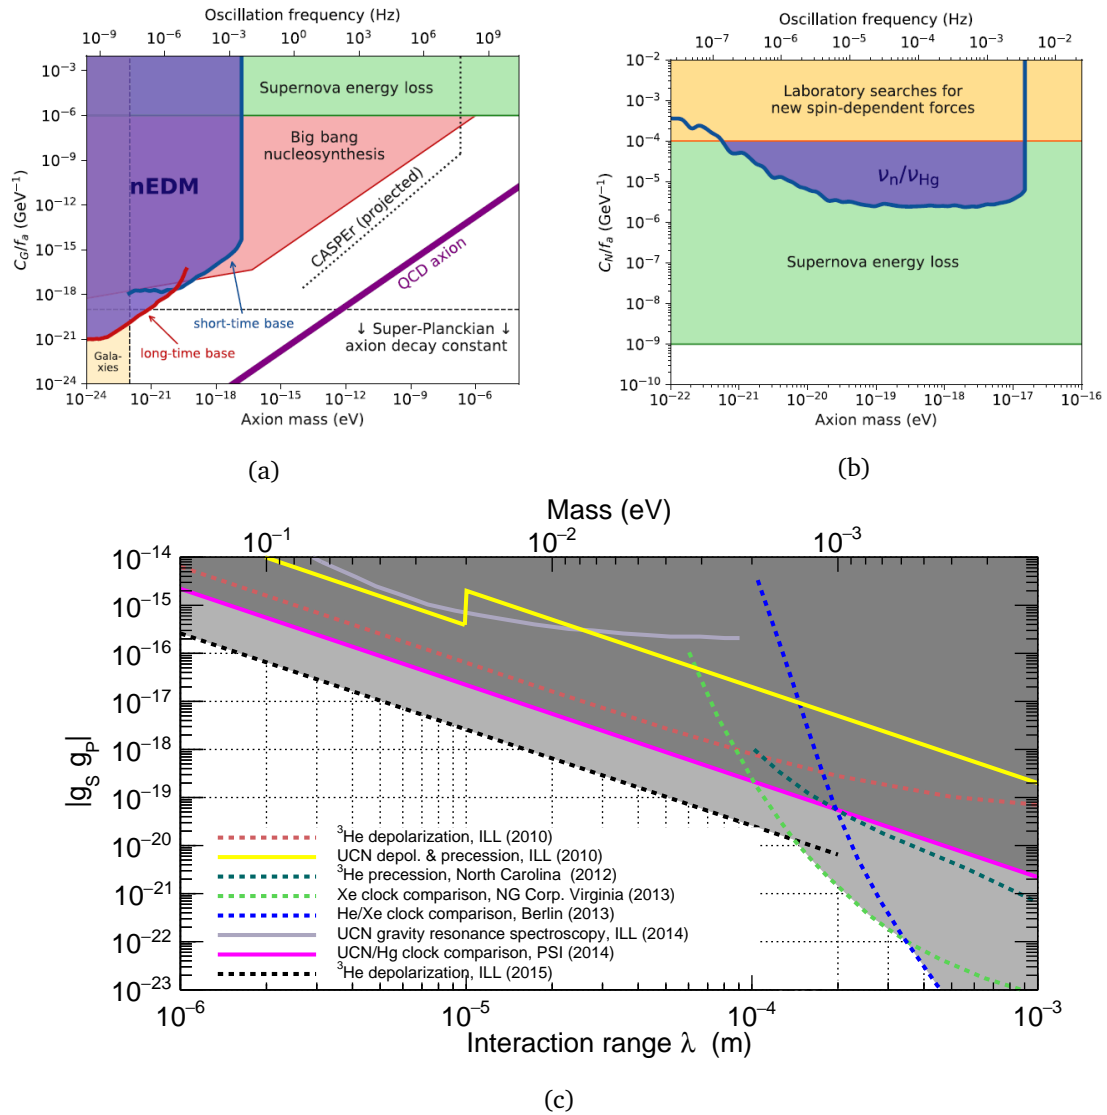

Figure 28.1: (a) first laboratory-based limit on the axion-gluon coupling C_G taken from [3]. (b) limit on the axion-nucleon coupling C_N . (c) shows the limit established in [10] for the scalar-pseudoscalar coupling for axion or axion-like particle (pink solid line). In this plot, reproduced from [11] (courtesy M. Guigue), the solid lines are constraints established with free neutrons (dark grey excluded zone) while dot-dashed lines are constraints established on bound nucleons (light grey excluded zone).

76 A limit on a completely different mass range can be obtained searching for a scalar-pseudo-
 77 scalar coupling between the polarized neutrons and the unpolarized nuclei in the electrodes
 78 of the storage chamber. Due to gravity, the neutron density is higher close to the bottom
 79 electrode so globally the effective field \vec{b} in (28.2) due to the two electrodes does not cancel
 80 out for neutrons (it does for mercury atoms whose density is homogeneous). We searched
 81 for the effective field \vec{b} as a shift in the \mathcal{R} ratio correlated with the direction of the applied
 82 magnetic field. The obtained limit is shown in Figure 28.1c and compared with other limits
 83 established using atoms.

84 28.3 Search for mirror neutrons

85 Lee and Yang suggested [12] that parity symmetry in the weak interaction could be restored by
 86 the existence of a parity conjugated copy of the same set of weakly interacting particles. It was
 87 shown later [13] that SM particles would not interact with their *mirror* counterparts (SM') via
 88 SM forces, and SM' would have its own interactions. However there may exist interactions
 89 beyond the SM, between neutral SM and SM' particles. The idea that by the introduction of
 90 mirror matter, parity and time reversal symmetries could be restored in the weak interactions,
 91 and thus in a global sense as well, was detailed further in [14, 15]. Berezhiani and others
 92 proved that the interaction of SM and SM' particles could answer several open questions in
 93 physics: (i) mirror matter could be a viable dark matter candidate [16–21], (ii) it would
 94 provide a mechanism to help solve sterile neutrino anomalies [22–24], (iii) SM neutrinos
 95 could be endowed with mass [23, 25], (iv) it could open up additional channels of CP and
 96 baryon number violation, helping to explain baryogenesis and the baryon asymmetry of the
 97 universe [26, 27], (v) it could provide a mechanism to relax the Greisen-Zatsepin-Kuzmin
 98 (GZK) limit on cosmic rays [28, 29]. A comprehensive review can be found in [16, 30–32].

99 In [33] Berezhiani et al. showed that as long as neutrons and their mirror counterparts
 100 have the same mass, decay width and gravitational potential, application of a magnetic field,
 101 B , equal to a mirror magnetic field, B' , in the same place can induce a degeneracy between
 102 the SM and SM' states, and an $n - n'$ oscillation would be possible. The time constant for the
 103 coupling, $\tau_{nn'}$, could be as low as several seconds. By inducing or destroying the degeneracy,
 104 this oscillation could be made visible by means of scanning the applied magnetic field in the
 105 experiments.

106 Pokotilovski proposed [34] that if ultracold neutrons (UCN) would be stored, and they
 107 would oscillate into the mirror state, then by such disappearance experiments a signature to
 108 mirror states could be probed. First experiments with UCN [35–37] obtained a limit under the
 109 assumption of a mirror magnetic field $B' = 0$ of $\tau_{nn'} > 448$ s (90% C.L.) [37]. Reference [38]
 110 relaxed the conditions to $B' \neq 0$ and set a constraint of $\tau_{nn'} > 12$ s for $0.4 \mu\text{T} < B' < 12.5 \mu\text{T}$
 111 (95% C.L.). In [39], Berezhiani *et al.* further analysed the above experiments and reported
 112 signal-like anomalies for $n - n'$ oscillation when $B' \neq 0$. Reference [40] again identifies statisti-
 113 cally significant signals: a 3σ signal from the data in [35], a 5.2σ signal from data in [36, 37],
 114 and a 2.5σ signal in [40].

115 The potential signals of [39] motivated a new measurement at PSI by the neutron electric
 116 dipole moment (nEDM) collaboration [4]. The nEDM apparatus was re-purposed for these
 117 storage measurements using unpolarized neutrons in order to increase statistics. The B mag-
 118 netic field was alternately switched off and on using both polarities, thus modifying the degen-
 119 eracy between the SM and the assumed SM' energy levels. We did not observe any statistically
 120 significant changes in the stored UCN counts from different magnetic field settings, and set
 121 constraints on the parameters of $n - n'$ oscillation.

122 The parameter space of the mirror magnetic field, B' and $(\tau_{nn'}/\sqrt{\cos\beta})$, constrained by
 123 different experiments is shown in Figure 28.2 [4]. The angle between the assumed B' and the
 124 applied magnetic field B is denoted by β . We also plotted the results from previous searches,
 125 including the signal-like anomalies detailed in the caption.

126 As in [33], we considered that the mirror magnetic field B' and β are constant at the
 127 experiment site. The constraints in [33, 35–40] were measured at the Institute Laue-Langevin
 128 (ILL) in Grenoble. The experiment in [4] was performed at PSI. We worked with the natural
 129 assumption that a mirror magnetic field created within the Earth [33] displays approximate
 130 rotational symmetry around the Earth's rotation axis, similar to the Earth's magnetic field.
 131 Then its components would only change on a level of 5% between ILL and PSI [?], and similarly
 132 in time, causing a negligible offset on the B' axis of Figure 28.2.

133 The solid orange curve in Figure 28.2 excludes all signal spots (see black dots) reported

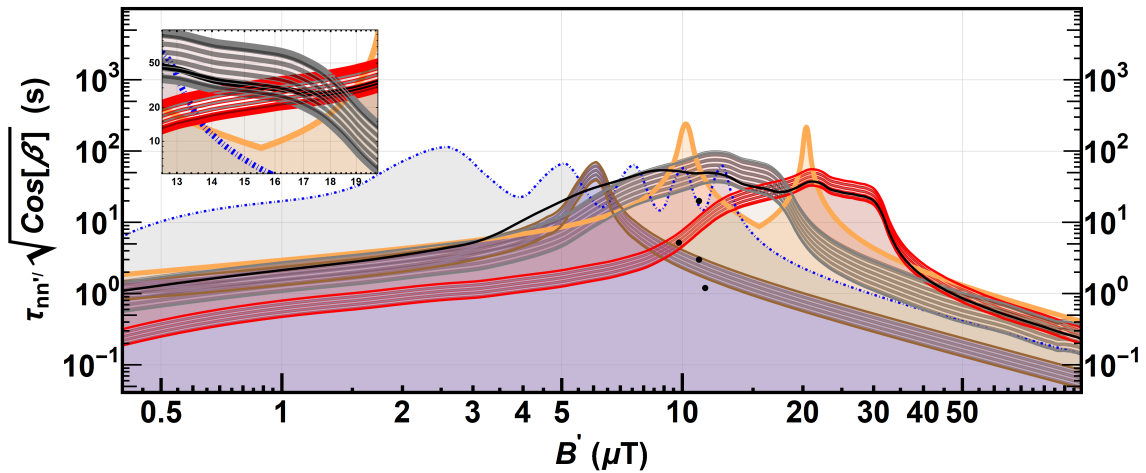

Figure 28.2: Lower limits [4] on the $n - n'$ oscillation time, $\tau_{nn'}$ at 95% C.L. while assuming $B' \neq 0$. From the asymmetry analysis, the solid orange curve represents the lower limit on $(\tau_{nn'}^{B' \neq 0} / \sqrt{\cos \beta})$. The black curve is the global constraint calculated in [40]. The dot-dashed blue curve represents the lower limit imposed using data in [38] by [40]. The three striped regions are the signals (95% C.L.): (i) the red striped region, is the signal region calculated in [39, 40] from the 5.2σ anomaly in [37]; (ii) the brown striped region is the signal calculated in [39, 40] from the 3σ anomaly in [35]; and (iii) the gray striped region is the signal from the 2.5σ anomaly observed in [40]. The black dots indicate the the solution consistent with the statistically significant signals as reported in [39].

134 in [39], for which the experiment at PSI was optimized in 2017. The three signal bands
 135 in [37, 39, 40] exclude each other since they don't overlap at the same mirror magnetic field,
 136 B' . Our analysis excludes three of the five areas where at least two of the signal bands overlap.

137 28.4 Outlook

138 Competitive searches for dark matter have been conducted using the nEDM spectrometer over
 139 the last decade. More ideas are still being explored to extend the limits on axion-like particles:
 140 a limit on the oscillating EDM signal at higher frequency (axion mass range up to 10^{-15} eV) is
 141 under study and dedicated data to push the limit of reference [10] are being analyzed.

142 Additionally, similar searches of axion-like particles are planned with the next generation
 143 n2EDM apparatus making use of the much improved sensitivity in the frequency measurements
 144 and of the better control over systematic effects. The not yet excluded regions of the signal
 145 bands of [40] for mirror neutrons will be a focus of future efforts.
