Abstract

This paper recalls the main achievements of the nTRV experiment which measured two components of the transverse polarization (σ_{T_1} , σ_{T_2}) of electrons emitted in the β -decay of polarized, free neutrons and deduced two correlation coefficients, R and N , that are sensitive to physics beyond the Standard Model. The value of time-reversal odd coefficient R , $0.004 \pm 0.012 \pm 0.005$, significantly improved limits on the relative strength of imaginary scalar coupling constant in the weak interaction. The value obtained for the time-reversal even correlation coefficient N , $0.067 \pm 0.011 \pm 0.004$, agrees with the Standard Model expectation, providing an important sensitivity test of the electron polarimeter. One of the conclusions of this pioneering experiment was that the transverse electron polarization in the neutron β -decay is worth more systematic exploring by measurements of yet experimentally not attempted correlation coefficients such as H , L , S , U and V . This article presents a brief outlook on that questions.

15.1 Introduction

Beta decay theory was firmly established about six decades ago and became a part of the Standard Model (SM). It describes the semi-leptonic and strangeness-conserving processes in the 1-st particle generation mediated by charged W -boson exchange. Among the empirical foundations of the electroweak sector of the SM, the assumptions of maximal parity violation, the vector and axial-vector character, and massless neutrinos are directly linked to nuclear and neutron beta decay experiments. In this way, nuclear and neutron beta decay have played a central role in the development of the weak interaction theory. Beta decay experiments with increasing precision still confirm the first two assumptions – only the neutrino masses have been shown to be finite. However, many open questions remain such as the origin of parity violation, the hierarchy of fermion masses, the number of particle generations, the mechanism of CP violation, and the unexplained large number of parameters of the theory. The CKM matrix induced mechanism of CP violation reported for heavier systems in [1, 2] is far too weak to explain the matter-antimatter asymmetry of universe so that new CP- or T-violation sources are subject of intensive searches. In particular, interesting are processes in the systems built of light quarks with vanishingly small contributions of the CKM matrix mechanism such as nuclear beta decay. Experiments with free neutrons play a particularly important role since their interpretation is not biased with nuclear and atomic structure uncertainties. In addition,

the effects of electromagnetic interaction of charged decay products in the final state (proton, electron), which can mimic T-violation, are small and can be reliably calculated [3–5].

The nTRV project at PSI, was the first experimental search for the real and imaginary parts of the scalar and tensor couplings using the measurement of the transverse polarization of electrons emitted in the free neutron decay. There are very few measurements of this observable in general [6,7], and only two in nuclear beta decays. One of them, for the ^8Li system [8], provides the most stringent limit on the tensor coupling constants of the weak interaction.

According to [9], the decay rate distribution from polarized neutrons as a function of electron energy (E) and momentum (\mathbf{p}) is proportional to:

$$\omega(\mathbf{J}, \hat{\boldsymbol{\sigma}}, E, \mathbf{p}) \propto 1 + \frac{\langle \mathbf{J} \rangle}{J} \cdot \left(A \frac{\mathbf{p}}{E} + N \hat{\boldsymbol{\sigma}} + R \frac{\mathbf{p} \times \hat{\boldsymbol{\sigma}}}{E} \right) + \dots \quad (15.1)$$

where $\frac{\langle \mathbf{J} \rangle}{J}$ ($J = |\mathbf{J}|$) is the neutron polarization, $\hat{\boldsymbol{\sigma}}$ is the unit vector onto which the electron spin is projected, and A is the beta decay asymmetry parameter. N and R are correlation coefficients which, for neutron decay with usual SM assumptions: $C_V = C'_V = 1$, $C_A = C'_A = \lambda = -1.276$ [10] and allowing for a small admixture of scalar and tensor couplings C_S , C_T , C'_S , C'_T , can be expressed as:

$$N = -0.218 \cdot \text{Re}(\mathfrak{S}) + 0.335 \cdot \text{Re}(\mathfrak{T}) - \frac{m}{E} \cdot A, \quad (15.2)$$

$$R = -0.218 \cdot \text{Im}(\mathfrak{S}) + 0.335 \cdot \text{Im}(\mathfrak{T}) - \frac{m}{137p} \cdot A, \quad (15.3)$$

where $\mathfrak{S} \equiv (C_S + C'_S)/C_V$, $\mathfrak{T} \equiv (C_T + C'_T)/C_A$ and m is the electron mass. The SM value of N is finite, $N \approx -\frac{m}{E} \cdot A \approx 0.068$, and well within reach of this experiment. Its determination provides an important test of the experimental sensitivity. The R correlation coefficient vanishes in the lowest order SM calculations. It becomes finite if final state interactions are included, $R_{FSI} \approx -\frac{m}{137p} \cdot A \approx 0.0006$, two orders of magnitude below the sensitivity of this experiment. A larger value of R would provide evidence for the existence of exotic couplings, and a new source of time reversal violation (TRV). Using Mott polarimetry, both transverse components of the electron polarization can be measured simultaneously: σ_{T_1} contained in the decay plane defined by the neutron spin and electron momentum associated with N , and σ_{T_2} perpendicular to the decay plane and associated with R .

15.2 Experiment

The experiment was carried out at the high intensity cold neutron beam line [11] at the neutron source SINQ of the Paul Scherrer Institute, Villigen, Switzerland. The final result is based on the analysis of two data sets collected in 2006 and 2007. It profits additionally from the experience gained during another two test runs performed in 2003 and 2004. Each of those measurements featured slightly different basic conditions such as beam polarization, Mott foil thickness, spin holding magnetic field and collected statistics.

Applied detector setup was left-right symmetric. Two identical systems of detectors were arranged in planar configuration on each side of the decay volume (Figure 15.1). Each of them consisted of a multi-wire proportional chamber (MWPC) for tracking of the electron trajectories and a scintillator hodoscope for electron energy measurement. Between these detectors a removable, remotely controlled, Mott scatterer (1-2 μm Pb layer evaporated on a 2.5 μm thick Mylar foil) was installed. The whole structure was mounted inside a large-volume dipole magnet providing a homogeneous vertical spin-holding field of 0.5 mT within the beam fiducial volume. A system of two RF-spin flippers (not shown in Figure 15.1) was used to control the orientation of the neutron beam polarization, reversing it at a regular time intervals, typically every 16 s.

Figure 15.1: Schematic top view of the experimental setup. An electron V-track event seen by both MWPCs and scintillator on one side is indicated in red [12].

82 Scintillator hodoscopes, formed by six 10-mm-thick and 60-cm-long plastic scintillator
 83 slabs were used for the electron energy reconstruction with the resolution of 33 keV at 500 keV.
 84 As the light signal produced in each segment was read out from its both ends, the up-down
 85 asymmetry has been used to determine the vertical hit position with a resolution of about 6
 86 cm. The width of each segment (10 cm) of this hodoscope provided an approximate estimate
 87 of the position in horizontal direction (z-coordinate). Matching the position information from
 88 the MWPC and that from the scintillator hodoscope considerably helped to reduce background
 89 and random coincidences.

90 A 1.3-m-long multi-slit ${}^6\text{Li}$ -based collimator defined the beam cross section to $4 \times 16 \text{ cm}^2$ at
 91 the entrance of the Mott polarimeter. The beam was transported in pure helium at atmospheric
 92 pressure and the whole surface of the decay chamber was lined with ${}^6\text{Li}$ loaded polymer. The
 93 total flux of the collimated beam was typically about 10^{10} neutrons/sec.

94 Dedicated measurement was performed to study the beam polarization as a function of
 95 neutron wavelength and position [11]. It showed a substantial dependence of polarization on
 96 the position in the beam fiducial volume. As a consequence the average beam polarization,
 97 necessary for the evaluation of the N - and R -correlation coefficients, was extracted from the
 98 observed decay asymmetry using the beta decay asymmetry parameter $A = -0.1196 \pm 0.0002$
 99 [10] measured accurately in other experiments. This approach automatically accounts for
 100 the position-dependent beam density and polarization as well as for the detector acceptance.
 101 For this analysis, a large sample of single track events corresponding to electrons from neu-
 102 trons decay (with only one reconstructed track segment on the triggering scintillator side) was
 103 recorded, using a dedicated prescaled trigger. The main event trigger was used to identify and
 104 record all V-track candidates: events with two reconstructed segments on one side (indicat-
 105 ing at Mott scattering from lead) and one segment accompanied by a scintillator hit on the
 106 opposite side, (see Figure 15.1). For more details on experimental setup, beam quality and
 107 performance of the detectors see [13].

108 The following asymmetries were analyzed to extract the beam polarization, P :

$$\mathcal{E}(\beta, \gamma) = \frac{N^+(\beta, \gamma) - N^-(\beta, \gamma)}{N^+(\beta, \gamma) + N^-(\beta, \gamma)} = P\beta A \cos(\gamma), \quad (15.4)$$

Figure 15.2: Background-corrected experimental energy distributions (shaded areas) of (a) the single-track and (b) V-track events compared with simulations. (c) Background contribution (shaded) to vertex x -coordinate distribution of V-track events. The arrow indicates the Mott foil position [12].

109 where N^\pm are experimental, background-corrected counts of single tracks sorted in 4 bins of
 110 the electron velocity β , and 15 bins of the electron emission angle γ with respect to the neutron
 111 polarization direction. The sign in the superscripts reflects the beam polarization direction.

112 A comparison between the measured and MC simulated energy spectra for direct and Mott-
 113 scattered electrons is shown in Figure 15.2 a and b, respectively. Electronic thresholds are not
 114 included in the simulation – this is why the measured and simulated distributions do not match
 115 at the low energy side.

116 Another set of asymmetries was used to extract the N and R correlation coefficients :

$$\mathcal{A}(\alpha) = \frac{n^+(\alpha) - n^-(\alpha)}{n^+(\alpha) + n^-(\alpha)}, \quad (15.5)$$

117 where n^\pm represent background-corrected experimental numbers of counts of V-track events,
 118 sorted in 12 bins of α , the angle between electron scattering and neutron decay planes. In
 119 the case of V-track events, beside the background discussed previously, events for which the
 120 scattering took place in the surrounding of the Mott-target provide an additional source of
 121 background. Figure 15.2 c shows the distribution of the reconstructed vertex positions in
 122 the x -direction for data collected with and without the Mott foil. The distribution clearly
 123 peaks at the foil position. This relatively broad distribution is a result of extrapolation of
 124 two electron track segments crossing at relatively small angle ($20^\circ - 60^\circ$). Additionally, the
 125 electron straggling effects contribute to this broadening. The “foil-out” distribution has been
 126 scaled appropriately by a factor deduced from the accumulated neutron beam.

127 It can be shown [13] that

$$\mathcal{A}(\alpha) - P\bar{\beta}A\bar{\mathcal{F}}(\alpha) = P\bar{S}(\alpha) [N\bar{\mathcal{G}}(\alpha) + R\bar{\beta}\bar{\mathcal{H}}(\alpha)], \quad (15.6)$$

128 where the kinematical factors $\bar{\mathcal{F}}(\alpha)$, $\bar{\mathcal{G}}(\alpha)$, and $\bar{\mathcal{H}}(\alpha)$ represent the average values of the quan-
 129 tities $\hat{\mathbf{J}} \cdot \hat{\mathbf{p}}$, $\hat{\mathbf{J}} \cdot \hat{\boldsymbol{\sigma}}$ and $\hat{\mathbf{J}} \cdot \hat{\mathbf{p}} \times \hat{\boldsymbol{\sigma}}$, respectively, \bar{S} is the effective analyzing power of the electron
 130 Mott scattering, known in the literature as “Sherman function”, and the bar over a letter indi-
 131 cates event-by-event averaging. The term $P\bar{\beta}A\bar{\mathcal{F}}$ accounts for the β -decay-asymmetry-induced

Figure 15.3: Left panel: experimental asymmetries \mathcal{A} corrected for the $P\bar{\beta}A\bar{\mathcal{F}}$ term for the 2007 data set as a function of α (defined in text). The solid line illustrates a two-parameter (N, R) least-square fit to the data. The indicated errors are statistical. Right panel: geometrical factors $\bar{\mathcal{F}}(\alpha)$, $\bar{\mathcal{G}}(\alpha)$ and $\bar{\mathcal{H}}(\alpha)$ for the same data set [12].

132 nonuniform illumination of the Mott foil. Since the $\bar{\beta}$ and $\bar{\mathcal{F}}$ are known precisely from event-
 133 by-event averaging, the uncertainty of this term is dominated by the error of the average beam
 134 polarization P .

135 Mean values of the effective analyzing powers as a function of electron energy, scattering
 136 and incidence angles were calculated using the Geant 4 simulation framework [14], following
 137 guidelines presented in [15, 16]. This approach accounts properly for the atomic structure,
 138 nuclear size effects as well as the effects introduced by multiple scattering in thick foils.

139 The systematic uncertainty is dominated by the effects introduced by the background sub-
 140 traction procedure, connected with the choice of the geometrical cuts defining event classes
 141 “from-beam” and “off-beam”. To estimate this effect, the cuts were varied in a range limited
 142 solely by the geometry of the apparatus. Because the radio-frequency of the spin flippers
 143 was a small source of noise in the readout electronics, tiny spin-flipper-correlated dead time
 144 variations were observed. The result was corrected for this effect.

145 The asymmetries as defined in (15.4) and (15.5) have been calculated for events with
 146 energies above the neutron β -decay end-point energy and for events originating outside of
 147 the beam fiducial volume: they were found to be consistent with zero within the statistical
 148 accuracy, which proves that the data analysis was not biased e.g. with a spin-flipper-related
 149 false asymmetry.

150 A fit of the experimental asymmetries \mathcal{A} , corrected for the $P\bar{\beta}A\bar{\mathcal{F}}$ term for the experimental
 151 data set of 2007 is shown in Figure 15.3.

152 From the approximate symmetry of the detector with respect to the transformation $\alpha \rightarrow -\alpha$,
 153 it follows that $\bar{\beta}$, $\bar{\mathcal{S}}$ and the factors $\bar{\mathcal{F}}$, $\bar{\mathcal{H}}$ are all symmetric, while $\bar{\mathcal{G}}$ is an antisymmetric function
 154 of α (see Figure 15.3). This allows the extraction of the N coefficient from the expression [13]:

155

$$N \approx \frac{(r-1)}{(r+1)} \cdot \frac{1 - \frac{1}{2}(P\bar{\beta}A\bar{\mathcal{F}})^2}{P\bar{\mathcal{S}}\bar{\mathcal{G}}}, \quad r = \sqrt{\frac{n^+(\alpha)n^-(-\alpha)}{n^-(\alpha)n^+(-\alpha)}} \quad (15.7)$$

156 The advantage of this method is that the impact of uncertainty of the term $P\bar{\beta}A\bar{\mathcal{F}}$ is suppressed
 157 by a factor of about 60 compared to (15.6). The good agreement between the N values ob-
 158 tained in both ways enhances confidence in the extracted N and R coefficient values.

159 The systematic uncertainties in the evaluation of the R and N coefficients are dominated by
 160 effects introduced by the background subtraction procedure and the choice of specific values
 161 of the cuts that determine whether an individual event is attributed to “signal” or to “back-
 162 ground”. The impact of these effects was systematically studied for all data sets. Another
 163 systematic is related to the Mott-target mass distribution as it can influence the electron de-
 164 polarization leading to increased uncertainty of the effective Sherman function. Additional
 165 calibration measurements were performed to determine the Mott-target thickness distribution
 166 using the photon induced X-ray emission method [17]. A detailed description of the data
 167 analysis process can be found in [12, 18] together with the final result comprising all available
 168 experimental data.

$$N = 0.067 \pm 0.022_{\text{stat}} \pm 0.004_{\text{syst}}, \quad (15.8)$$

$$R = 0.004 \pm 0.012_{\text{stat}} \pm 0.005_{\text{syst}}. \quad (15.9)$$

169 This was the first determination of the N correlation coefficient in β -decay.

170 In Figure 15.4 the new results are included in exclusion plots containing all experimental
 171 information available from nuclear and neutron beta decays as surveyed in [19]. The upper
 172 plots contain the normalized scalar and tensor coupling constants \mathfrak{S} and \mathfrak{T} , while the lower
 173 plots correspond to the helicity projection amplitudes in the leptoquark exchange model, as
 174 defined in [20]. Although the achieved accuracy does not improve the already strong con-
 175 straints on the real part of the couplings (left panels), the result is consistent with the existing
 176 data and increases confidence in the validity of the extraction of R . For the imaginary part
 177 (right panels), the new experimental value of the R coefficient significantly constrains scalar
 178 couplings beyond the limits from all previous measurements. The result is consistent with the
 179 SM.

180 15.3 Outlook – the BRAND project

181 The successful determination of two transverse components of the polarization of electrons
 182 emitted in neutron decay in a pioneering and nearly optimal experiment led to the following
 183 conclusions: (i) it seems quite possible to decrease the systematic uncertainty by an order of
 184 magnitude using existing techniques, (ii) the transverse electron polarization can be studied
 185 in a more systematic way by correlating it with the electron momentum, the neutron spin, and
 186 also with the recoil proton momentum by constructing larger and higher acceptance detecting
 187 systems like e.g. proposed by [21] and operating with the highest intensity polarized cold
 188 neutron beam available. In this way, one can study seven correlation coefficients: H , L , N , R ,
 189 S , U and V where five of them (H , L , S , U , V) have never been experimentally studied:

$$\begin{aligned}
 \omega(E_e, \Omega_e, \Omega_{\bar{\nu}}) \propto 1 + & \\
 a \frac{\mathbf{p}_e \cdot \mathbf{p}_{\bar{\nu}}}{E_e E_{\bar{\nu}}} + b \frac{m_e}{E_e} + \frac{\langle \mathbf{J} \rangle}{J} \cdot \left[A \frac{\mathbf{p}_e}{E_e} + B \frac{\mathbf{p}_{\bar{\nu}}}{E_{\bar{\nu}}} + D \frac{\mathbf{p}_e \times \mathbf{p}_{\bar{\nu}}}{E_e E_{\bar{\nu}}} \right] + & \\
 \boldsymbol{\sigma}_{\perp} \cdot \left[H \frac{\mathbf{p}_{\bar{\nu}}}{E_{\bar{\nu}}} + L \frac{\mathbf{p}_e \times \mathbf{p}_{\bar{\nu}}}{E_e E_{\bar{\nu}}} + N \frac{\langle \mathbf{J} \rangle}{J} + R \frac{\langle \mathbf{J} \rangle \times \mathbf{p}_e}{J E_e} + \right. & \\
 \left. S \frac{\langle \mathbf{J} \rangle \cdot \mathbf{p}_e}{J E_e E_{\bar{\nu}}} + U \mathbf{p}_{\bar{\nu}} \frac{\langle \mathbf{J} \rangle \cdot \mathbf{p}_e}{J E_e E_{\bar{\nu}}} + V \frac{\mathbf{p}_{\bar{\nu}} \times \langle \mathbf{J} \rangle}{J E_{\bar{\nu}}} \right], & \quad (15.10)
 \end{aligned}$$

190 where $\boldsymbol{\sigma}_{\perp}$ represents a unit vector perpendicular to the electron momentum \mathbf{p}_e and $J = |\mathbf{J}|$.
 191 $\mathbf{p}_{\bar{\nu}}$ and $E_{\bar{\nu}}$ are the antineutrino momentum and energy, respectively.

192 The coefficients relating the transverse electron polarization to \mathbf{p}_e , $\mathbf{p}_{\bar{\nu}}$ and \mathbf{J} have several
 193 interesting features. They vanish for the SM weak interaction, and reveal the variable size
 194 of the electromagnetic contributions. For H and N , the electromagnetic contributions are of

Figure 15.4: Experimental bounds on the scalar vs. tensor normalized couplings (upper) and leptokuark exchange helicity projection amplitudes (lower panels) published in [12]. The gray areas represent the available to date empirical information as listed in [19], while the lines represent the limits resulting from the present experiment. Solid, dashed and dotted lines correspond to 1-, 2- and 3- sigma confidence levels, respectively, in analogy to decreasing intensity of the grey areas.

195 the order of 0.06, which can be used for an internal sensitivity check of the Mott polarimeter.
 196 Finally, the dependence on the real and imaginary parts of the scalar and tensor couplings
 197 alternates exclusively from one correlation coefficient to another with varying sensitivity. This
 198 feature allows a complete set of constraints to be determined from the neutron decay alone.

199 The idea of implementing such a complex measurement was proposed in [22]. An updated
 200 version of the measurement can be found in [23]. Presently, the first test run devoted to the
 201 verification of the applied detectors and techniques has been completed on the PF1B cold
 202 neutron beam at the Laue Langevin Institute in Grenoble, France (ILL).

203 15.4 EFT parameterization

204 In order to permit for sensitivity comparison of low-energy charged-current observables with
 205 measurements carried out at high-energy colliders, the model-independent effective field theory (EFT)
 206 framework is employed. This approach bridges the classical β -decay formalism with
 207 high-energy physics. The effective nucleon-level couplings C_i, C'_i ($i \in [V, A, S, T]$) can be gener-
 208 ally expressed as combinations of the quark-level parameters $\epsilon_i, \tilde{\epsilon}_i$ ($i \in [L, R, S, T]$) [25]. The
 209 real parts of the scalar and tensor couplings parameterize CP-conserving and imaginary parts –
 210 CP-violating contributions. The high energy BSM physics quantity that can be compared with
 211 β -decay observables is the cross section for electrons and missing transverse energy (MET) in
 212 $pp \rightarrow e \bar{\nu} + MET + \dots$ channel. Both have the same underlying partonic process: $\bar{u}d \rightarrow e \bar{\nu}$.
 213 Anticipating the experimental accuracy of about 5×10^{-4} for the transverse electron polariza-
 214 tion related correlation coefficients in the BRAND experiment one would obtain significantly
 215 tighter bounds on the real and imaginary parts of scalar and tensor coupling constants and,

Figure 15.5: Experimental bounds on the scalar vs. tensor couplings \mathfrak{S} , \mathfrak{T} from (15.2) (upper panels) and translated to EFT parameters ϵ_S , ϵ_T (lower panels) published in [23]. The gray areas represent the information deduced from available experiments as listed in [24], while the red lines represent the limits resulting from the correlation coefficients H , L , N , R , S , U and V measured with the anticipated accuracy of 5×10^{-4} . Solid, dashed and dotted lines correspond to 1-, 2- and 3- σ confidence levels, respectively, in analogy to decreasing intensity of the grey areas.

216 consequently, on ϵ_S and ϵ_T as shown in Figure 15.5. It should be noted that such limits would
 217 be competitive to those extracted from the analysis of 20 fb^{-1} CMS collaboration data collected
 218 at 8 TeV [26, 27] and even to the planned measurements at 14 TeV.
