## Abstract

We present a numerical quantum Monte Carlo (QMC) method for simulating the 3D phase transition on the recently proposed fuzzy sphere [Phys. Rev. X 13, 021009 (2023)]. By introducing an additional  $SU(2)$  layer degree of freedom, we reformulate the model into a form suitable for sign-problem-free QMC simulation. From the finite-size-scaling, we show that this QMC-friendly model undergoes a quantum phase transition belonging to the 3D Ising universality class, and at the critical point we compute the scaling dimensions from the state-operator correspondence, which largely agrees with the prediction from the conformal field theory. These results pave the way to construct sign-problem-free models for QMC simulations on the fuzzy sphere, which could advance the future study on more sophisticated criticalities.

## 20 1 Introduction

21 Critical phenomena emerging at classical and quantum phase transitions are of great interest  
 22 due to their experimental relevance and theoretical significance [1, 2]. Many critical phe-  
 23 nomena are believed to be described by conformal field theories (CFTs), which are strongly-  
 24 interacting and pose challenges for studies in higher space-time dimensions beyond 2D (i.e.,  
 25 1+1D). A recent method known as fuzzy (non-commutative) sphere regularization [3] has  
 26 been invented to investigate 3D (i.e., 2+1D) critical phenomena governed by 3D CFTs on a  
 27 cylindrical geometry represented as  $S^2 \times \mathbb{R}$ . Compared to traditional lattice regularization,  
 28 the fuzzy sphere regularization offers numerous advantages in the study of 3D CFTs, primarily  
 29 due to the utilization of radial quantization in  $S^2 \times \mathbb{R}$  [4, 5] as well as the exact preservation  
 30 of sphere  $SO(3)$  symmetry [6, 7], as convincingly demonstrated recently [3, 8–11].

31 Firstly, the fuzzy sphere enables direct access to information regarding the emergent con-  
 32 formal symmetry in the critical state [3, 10]. Secondly, it allows for the direct extraction of  
 33 various data of the CFTs, including numerous scaling dimensions of conformal primary op-  
 34 erators [3, 10], operator product expansion coefficients [8], and four-point correlators [9].  
 35 For instance, scaling dimensions can be computed directly from excitation energies of the sys-  
 36 tem, and their accuracy can be further improved using conformal perturbation [12]. Thirdly,  
 37 the fuzzy sphere scheme is applicable to a variety of 3D CFTs, including Ising [3],  $O(N)$   
 38 Wilson-Fisher,  $SO(5)$  deconfined phase transition [10], critical gauge theories [10], and de-  
 39 fect CFTs [11]. Lastly, the fuzzy sphere regularization exhibits an incredibly small finite-size  
 40 effect when the Hamiltonian is reasonably fine-tuned. These advantageous features of fuzzy  
 41 sphere regularization present an exciting opportunity to explore 3D CFTs with high efficiency,  
 42 accuracy, and comprehensiveness.

43 The fuzzy sphere regularization considers a microscopic quantum Hamiltonian modeling  
 44 fermions (with multiple flavors) on continuous spherical space and projecting fermions into the  
 45 lowest spherical Landau level [3, 6, 13]. In comparison with the regular lattice model, the fuzzy  
 46 sphere model preserves the continuous rotational symmetry exactly in the UV limit. Thanks to  
 47 the extremely small finite-size effect achieved through fine-tuning, numerical algorithms such  
 48 as exact diagonalization (ED) and density matrix renormalization group (DMRG) methods are  
 49 highly effective in studying the fuzzy sphere model of the 3D Ising CFT and  $SO(5)$  deconfined  
 50 phase transition. However, the computational cost of these two algorithms will eventually  
 51 grow exponentially with the system size. More importantly, for cases involving a large number  
 52 of fermion flavors, the computational costs of ED and DMRG quickly surpass practical resource  
 53 and time limitations. In these cases, it would be helpful to be able to study models on the fuzzy  
 54 sphere using a method that scales polynomially in time, such as quantum Monte Carlo (QMC).

55 The aim of this paper is to utilize the 3D Ising CFT as an example to demonstrate the  
 56 application of the QMC approach in studying 3D CFTs on the fuzzy sphere. A similar discussion  
 57 for the fuzzy torus model can be found in Ref. [13, 14]. In contrast to the fuzzy sphere Ising  
 58 model introduced in Ref. [3], we introduce an additional flavor index to the fermions, which  
 59 results in no sign problem for the QMC simulations. As a benchmark, we provide numerical

60 results of finite-size scaling, indicating that this model also belongs to the 3D Ising universality  
 61 class. Furthermore, we introduce observables that enable the extraction of energy gaps in the  
 62 spectrum corresponding to specific symmetry quantum numbers. This allows us to investigate  
 63 the presence of conformal symmetry at criticality and extract scaling dimensions through the  
 64 state-operator correspondence. Our numerical results for energy gaps are consistent with the  
 65 universality of the 3D CFT Ising model, albeit with a larger finite-size effect compared to the  
 66 previously studied fuzzy sphere Ising model [3]. In summary, we believe the QMC enriches  
 67 the arsenal to study the fuzzy sphere model.

68 This paper is organized as follows: in Section II we introduce the model and its sym-  
 69 metries, and we discuss how it can be implemented in auxiliary-field QMC simulations. We  
 70 also argue for why the simulations are sign-problem-free. In Section III we discuss finite-size-  
 71 scaling results and give evidence that the model is in the 3D Ising universality class, and we  
 72 discuss energy spectrum results and give evidence for emergent conformal symmetry. Section  
 73 IV contains our conclusions.

## 74 2 Model and Method

### 75 2.1 Review of fuzzy sphere regularization

76 The fuzzy sphere regularization considers fermions moving on a sphere in the presence of  
 77 a magnetic monopole with  $4\pi s$  flux sitting in the center of the sphere. In general, we can  
 78 consider multi-flavor fermions  $\psi_\alpha$  with the flavor index  $\alpha$ , described by a Hamiltonian,

$$H = H_{\text{kin}} + H_{\text{int}}. \quad (1)$$

79 Here  $H_{\text{kin}}$  is the kinetic term of fermions, and  $H_{\text{int}}$  is an interaction which takes forms such as  
 80 a density-density interaction,

$$\int d^2\vec{r}_1 d^2\vec{r}_2 U(\vec{r}_1 - \vec{r}_2) n^a(\vec{r}_1) n^b(\vec{r}_2), \quad (2)$$

81 where  $n^a(\vec{r}) = \psi^\dagger(\vec{r})_\alpha \psi(\vec{r})_\beta M_{\alpha\beta}^a$  and  $M^a$  is a matrix defined in the fermion flavor space.  
 82  $U(\vec{r}_1 - \vec{r}_2)$  is a rotationally invariant interaction, and we take it to be short ranged such as  
 83  $\delta(\vec{r}_1 - \vec{r}_2)$  and  $\nabla^2 \delta(\vec{r}_1 - \vec{r}_2)$ .

84 The energy levels of  $H_{\text{kin}}$  form quantized Landau levels, whose wave-functions are de-  
 85 scribed by the monopole Harmonics (i.e. spin-weighted spherical Harmonics)  $Y_{n+s,m}^{(s)}(\theta, \varphi)$  [15],  
 86 with  $n = 0, 1, \dots$  as the Landau level index and  $(\theta, \varphi)$  as the spherical coordinates. Each Lan-  
 87 dau level has an energy  $E_n = [(n + 1/2) + n(n + 1)/2s] \omega_c / 2\pi$ , with the cyclotron frequency  
 88  $\omega_c$  [6, 16]. The states of each Landau level have an angular momentum  $L = s + n$ , hence  
 89 they are  $(2s + 2n + 1)$ -fold degenerate, which can be labeled by the quantum number of the  
 90  $\mathbf{z}$ -component of the angular momentum  $L^z$ ,  $m = -s - n, -s - n + 1, \dots, s + n$ . We consider  
 91 the limit that  $H_{\text{kin}} \gg H_{\text{int}}$  such that we can project the system into the lowest Landau level  
 92 (LLL). The annihilation operator  $\psi(\theta, \varphi)$  on the LLL can be written as

$$\psi_\alpha(\theta, \varphi) = \frac{1}{\sqrt{N}} \sum_{m=-s}^s \bar{Y}_{s,m}^{(s)}(\theta, \varphi) c_{m,\alpha}, \quad (3)$$

93 where  $c_{m,\alpha}$  stands for the annihilation operator of Landau orbital  $m$ , and it is independent of  
 94 coordinates  $(\theta, \varphi)$ .  $N = 2s + 1$  is the number of orbitals, playing the role of area of the 2D  
 95 space. The prefactor  $1/\sqrt{N}$  ensures that the density operator,

$$n^a(\theta, \varphi) = \frac{1}{N} \sum_{m_1, m_2} Y_{s,m_1}^{(s)} \bar{Y}_{s,m_2}^{(s)} c_{m_1,\alpha}^\dagger c_{m_2,\beta} M_{\alpha\beta}^a, \quad (4)$$

96 is an intensive quantity.

97 Under this LLL projection Eq. (3), any rotation invariant density-density interaction in the  
98 form of eq. (2) can be written as the Haldane pseudopotentials [6] in terms of second quantized  
99 fermion operators,

$$\sum_{m_1, m_2, m_3, m_4} V_{m_1, m_2, m_3, m_4} (c_{m_1, \alpha}^\dagger M_{\alpha\beta}^a c_{m_4, \beta}) (c_{m_2, \eta}^\dagger M_{\eta\gamma}^b c_{m_3, \gamma}) \quad (5)$$

100 with

$$V_{m_1, m_2, m_3, m_4} = \delta_{m_1+m_2, m_3+m_4} \sum_{l=0}^{2s} V_l (4s - 2l + 1) \times \begin{pmatrix} s & s & 2s-l \\ m_1 & m_2 & -m_1-m_2 \end{pmatrix} \begin{pmatrix} s & s & 2s-l \\ m_4 & m_3 & -m_3-m_4 \end{pmatrix}, \quad (6)$$

101 where  $\begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m_2 & m_3 \end{pmatrix}$  is the Wigner  $3j$ -symbol.  $V_l$  are numbers whose values are specifically  
102 depending on the form of the interaction  $U(\vec{r}_1 - \vec{r}_1)$ . For the remainder of this work, we focus  
103 on  $U(\vec{r}_1 - \vec{r}_1) = U(\Omega_{12}) = \frac{g_0}{N} \delta(\Omega_{12}) + \frac{g_1}{N^2} \nabla^2 \delta(\Omega_{12})$  with  $\delta(\Omega_{12}) = \delta(\varphi_1 - \varphi_2) \delta(\cos \theta_1 - \cos \theta_2)$ .  
104 The corresponding Haldane pseudo-potentials are

$$V_0 = \frac{2s+1}{4s+1} g_0 - \frac{s}{4s+1} g_1, \quad V_1 = \frac{s}{4s-1} g_1, \quad V_{l \geq 2} = 0. \quad (7)$$

105 To realize the  $2+1$ D Ising transition, Ref. [3] introduced a Hamiltonian that has two flavors  
106 of fermions  $\psi^\dagger = (\psi_\uparrow^\dagger, \psi_\downarrow^\dagger)$  with their interaction,

$$H = \int N^2 d\Omega_1 d\Omega_2 U(\Omega_{12}) [n^0(\theta_1, \varphi_1) n^0(\theta_2, \varphi_2) - n^z(\theta_1, \varphi_1) n^z(\theta_2, \varphi_2)] - h \int N d\Omega n^x(\theta, \varphi), \quad (8)$$

107 where  $\Omega = (\theta, \varphi)$  is a spherical coordinate and  $n^a(\theta, \varphi) = \psi^\dagger(\theta, \varphi) \sigma^a \psi(\theta, \varphi)$  is a local  
108 density operator with  $\sigma^{x,y,z}$  being Pauli matrices,  $\sigma^0 = I_{2 \times 2}$ . The first term behaves like an  
109 Ising ferromagnetic interaction, while the second term is the transverse field.

110 It is straightforward to solve the second quantized Hamiltonian Eq. (5) using unbiased  
111 numerical algorithm such as the ED and the DMRG, although their computational costs grow  
112 exponentially with the system size  $N = 2s + 1$ . So it is highly desirable to develop QMC  
113 method for the simulation of a fuzzy sphere model, and it is the focus of this paper.

114 It is worth mentioning why the LLL projection leads to a fuzzy sphere. We can consider the  
115 projection of the coordinates of a unit sphere, denoted as  $x = (\sin \theta \cos \varphi, \sin \theta \sin \varphi, \cos \theta)$ .  
116 After the projection, the coordinates are transformed into  $(2s + 1) \times (2s + 1)$  matrices, where  
117  $(X)_{m_1, m_2} = \int d\Omega x \bar{Y}_{s, m_1}^{(s)}(\Omega) Y_{s, m_2}^{(s)}(\Omega)$ . These matrices satisfy the following relations:

$$[X_i, X_j] = \frac{1}{s+1} i \epsilon_{ijk} X_k, \quad \sum_{i=1}^3 X_i X_i = \frac{s}{s+1} \mathbf{1}_{2s+1}. \quad (9)$$

118 The fact that the three coordinates satisfy the  $SO(3)$  algebra formally defines a fuzzy sphere  
119 [7]. It is interesting to note that in the limit as  $s \rightarrow \infty$ , the fuzziness disappears and a unit  
120 sphere is recovered.

## 121 2.2 The density form of interaction

122 To facilitate QMC simulation, we would like to write the Hamiltonian in terms of the density  
123 operator in the angular momentum space  $n_{l,m}^a$ , defined as,

$$n^a(\theta, \varphi) = \frac{1}{N} \sum_{l,m} n_{l,m}^a Y_l^m(\theta, \varphi). \quad (10)$$

124 Here  $Y_l^m(\theta, \varphi)$  is the spherical harmonics, with  $m = -l, -l+1, \dots, l$  and  $l \in \mathbb{Z}$ .  $n_{l,m}^a$  can be  
125 obtained using the spherical harmonic transformation,

$$\begin{aligned} n_{l,m}^a &= N \int d\Omega \bar{Y}_l^m(\theta, \varphi) n^a(\theta, \varphi) \\ &= N \sqrt{\frac{2l+1}{4\pi}} \sum_{m_1=-s}^s (-1)^{3s+m_1} \begin{pmatrix} s & l & s \\ -m_1 & m & m_1-m \end{pmatrix} \\ &\quad \times \begin{pmatrix} s & l & s \\ -s & 0 & s \end{pmatrix} c_{m_1,\alpha}^\dagger c_{m_1-m,\beta} M_{\alpha\beta}^a \end{aligned} \quad (11)$$

126 To have the term  $\begin{pmatrix} s & l & s \\ -m_1 & m & m_1-m \end{pmatrix}$  non-vanishing, we should have  $l \leq 2s$ . One can show  
127  $n_{l,m}^\dagger = (-1)^m n_{l,-m}$ .

128 In this context, it is convenient to decompose the potential  $U(\theta_{12}) = \sum_l \frac{2l+1}{4\pi} U_l P_l(\cos \theta_{12})$   
129 using the Legendre polynomials,  $P_l(\cos \theta_{12}) = \frac{4\pi}{2l+1} \sum_{m=-l}^l \bar{Y}_l^m(\Omega_1) Y_l^m(\Omega_2)$ , such that the  
130 interaction terms take the form

$$\begin{aligned} &\int N^2 d\Omega_1 d\Omega_2 U(\theta_{12}) n^a(\theta_1, \varphi_1) n^b(\theta_2, \varphi_2) \\ &= \sum_{l=0}^{2s} U_l \sum_{m=-l}^l (n_{l,m}^a)^\dagger n_{l,m}^b, \end{aligned} \quad (12)$$

131 with the coefficients  $U_l = g_0/N - l(l+1)g_1/N^2$ .

## 132 2.3 Four component fuzzy sphere model

133 In comparison to Ref. [3], we consider four flavors of fermions,  $\psi^\dagger = (\psi_{\uparrow,+}^\dagger, \psi_{\uparrow,-}^\dagger, \psi_{\downarrow,+}^\dagger, \psi_{\downarrow,-}^\dagger)$ ,  
134 i.e., we introduce an additional ‘‘layer’’ degree of freedom (+, -). The Pauli-matrices  $\sigma^i$  and  
135  $\tau^i$  act on the spin ( $\uparrow, \downarrow$ ) and layer indices, respectively. Let us define the operators  $n_{l,m}^0$  and  
136  $n_{l,m}^z$  according to Eq. (11) with  $M^0 = \sigma^0 \tau^0$  and  $M^z = \sigma^z \tau^0$ , respectively. The Hamiltonian  
137 reads

$$\begin{aligned} H &= \sum_{l=0}^{2s} U_l \sum_{m=-l}^l \left[ (n_{l,m}^0)^\dagger n_{l,m}^0 - (n_{l,m}^z)^\dagger n_{l,m}^z \right] \\ &\quad + h \sum c_m^\dagger \sigma^x \tau^0 c_m, \end{aligned} \quad (13)$$

138 and the interaction favors a ferromagnetic state for  $g_0, g_1 > 0$ .

139 There are four symmetries of this model, which are

140 1. Ising  $\mathbb{Z}_2$  symmetry:  $c_m \rightarrow \sigma^x \tau^0 c_m$ .

Figure 1: Order parameter data for  $V_0 = 0.5564$  and  $V_1 = 0.1$ , which shows evidence for a continuous phase transition consistent with that of the 3D Ising Model. (a) Binder ratio data showing a crossing that drifts somewhat in system size:  $N = 12$  and  $N = 14$  cross around  $h = 0.21$ , whereas  $N = 8$  and  $N = 10$  cross closer to  $h = 0.20$ . (b) Magnetization data showing consistent crossing between  $h = 0.21$  and  $h = 0.22$  for  $N = 10, 12, 14$ . Ising  $\Delta_\sigma = 0.518$  is assumed. (c) Magnetization data plotted along with a universal scaling function fit. Fixing  $\Delta_\sigma = 0.518$  and  $\Delta_\epsilon = 1.41$  (as shown in this figure) yields a good fit ( $\chi^2 = 1.305$ ) with  $h_c = 0.2129(8)$ , consistent with 3D Ising universality. Fitting using an  $h = 0.21$  estimate consistent with the Binder ratio and magnetization crossing data gives  $\Delta_\sigma = 0.49(2)$  and  $\Delta_\epsilon = 1.28(6)$ .

- 141 2.  $SO(3)$  sphere rotation symmetry:  $c_{m=-s,\dots,s}$  form the spin- $s$  representation of  $SO(3)$ .  
 142 3. Particle-hole symmetry:  $c_m \rightarrow i\sigma^y \tau^0 c_m^\dagger$ , and  $i \rightarrow -i$ .  
 143 4. Layer  $SU(2)$ : generated by  $c_m \rightarrow \sigma^0 \tau^{x,y,z} c_m$ .

144 The first three of these symmetries are the same as those of the two-flavor model studied  
 145 in [3]. The layer symmetry is an additional symmetry for the four flavors, which allows for  
 146 sign-problem-free QMC simulations of this model. At the Ising transition, the layer  $SU(2)$   
 147 degrees of freedom need to be gapped. We have verified this in Appendix C.

148 Before moving on, we remark that the four component fuzzy sphere model Eq. 13 is not a  
 149 simple product of the two-component model Eq. 8, so the phase transition point  $h_c$  of the four  
 150 component model is distinct from that of the two-component model. Nevertheless, we ensure  
 151 the universality of the four component model falls in the 3D Ising class, as shown below.

## 152 3 Results

### 153 3.1 QMC Simulations

154 We simulate the model, eq. (13), using projector auxiliary Quantum Monte Carlo (AFQMC).  
 155 To fit this goal, we rewrite the sums of quartic terms in the following way

$$\begin{aligned}
 U_l \sum_{m=-l}^l (n_{l,m}^a)^\dagger n_{l,m}^a &= U_l \sum_{m=-l}^l (-1)^m (n_{l,-m}^a) n_{l,m}^a \\
 &= \frac{U_l}{4} \sum_{m=-l}^l \left( (1+i)n_{l,m}^a + (1-i)(-1)^m n_{l,-m}^a \right)^2,
 \end{aligned} \tag{14}$$

156 where in the first equality we make use of the density operator identity

$$n_{l,m}^\dagger = (-1)^m n_{l,-m}. \quad (15)$$

157 The squared operators in the second line of (14) are Hermitian, and thus AFQMC as imple-  
158 mented in [17] is applicable. The projector we use is the half-filled solution to the model when  
159  $\mathbf{g}_0 = \mathbf{g}_1 = \mathbf{0}$ , where the Ising spins are polarized by the transverse field term  $\mathbf{h} \sum_m c_m^\dagger \sigma^x \tau^0 c_m$ .

160 Now we show, that the QMC simulation of this model is sign-problem-free. After the  
161 Hubbard-Stratonovich transformation, we have a prefactor of  $\sqrt{-\Delta \tau U_l / 4}$ . If  $\mathbf{g}_0 - \mathbf{g}_1 l(l+1)/(2s+1)$   
162 of the expression in (13) is always positive, then we get an extra factor of  $i$  for the  $n^0$  terms,  
163 which picks up a sign under antiunitary transformations. The antiunitary particle-hole trans-  
164 formation  $\mathcal{P}$ ,

$$\begin{aligned} c_m^\dagger &\rightarrow i \sigma^y \tau^0 c_m, & i &\rightarrow -i \\ n_{l,m}^z &\rightarrow (-1)^m n_{l,-m}^z \\ n_{l,m}^0 &\rightarrow -(-1)^m n_{l,-m}^0, \end{aligned} \quad (16)$$

165 is a symmetry with  $\mathcal{P}^2$ . Combined with the  $SU(2)$  layer symmetry, it guarantees the absence  
166 of the sign-problem in this model. [18]

167 In this particular model, we focus on the critical point that occurs in a regime where both  
168  $\mathbf{g}_0, \mathbf{g}_1 > \mathbf{0}$ . We have not proven in the discussion above that the absence of a sign problem  
169 occurs when instances of  $\mathbf{g}_0 - \mathbf{g}_1 l(l+1)/(2s+1)$  is positive for small  $l$  but is negative for  
170 large  $l$ , yet we encountered no sign problem in our simulations. One explanation may be that

171 the Wigner-3j prefactor  $\begin{pmatrix} s & l & s \\ -s & 0 & s \end{pmatrix}$  decays exponentially in  $l$ , causing a suppression of terms  
172 that change the overall prefactor signs in (13), and so the smallness of the couplings of these  
173 terms may be important.

174 Due to the nonlocal nature of the operators in (13), controlling Trotter discretization errors  
175 becomes a more demanding task, as observed in [14]. We alleviate some of these effects  
176 by adopting a stabilized second-order Trotter decomposition developed by Blanes et al., as  
177 discussed in [19]. The effectiveness of these alternate splitting schemes in the realm of AFQMC  
178 was shown in [20]. Furthermore, to implement the Wigner-3j prefactors efficiently, we utilize  
179 the software package detailed in [21].

180 Here we utilize QMC to compute the evolution of the order parameter and CFT dimen-  
181 sionless two-point correlators across the transition point, as well as extract energy gaps for  
182 the lowest lying states using time-displaced correlation functions (see Appendix B). While the  
183 Lowest Landau level basis has already been used for a QMC study in [22], the CFT-inspired  
184 use of time-displaced correlation functions and two-point correlators on the fuzzy sphere is  
185 new for QMC studies.

186 Below we will set  $V_1 = \mathbf{0.1}$ ,  $V_0 = \mathbf{0.5564}$ , and tune  $\mathbf{h}$  to realize a 2+1D Ising transition.  
187 We find this choice of  $(V_0, V_1)$  has a smaller finite size effect. By inverting the equations in  
188 (7), we have

$$\begin{aligned} \mathbf{g}_0 &= \frac{4s+1}{2s+1} V_0 + \frac{4s-1}{2s+1} V_1 \\ \mathbf{g}_1 &= \frac{4s-1}{s} V_1, \end{aligned} \quad (17)$$

189 so this corresponds to the region  $\mathbf{g}_0, \mathbf{g}_1 > \mathbf{0}$ .

### 190 3.2 Finite-Size-Scaling

191 To look for a phase transition, we begin with the order parameter for the Ising phase transition,  
192 which in the Landau Level basis (see Appendix A) is given by

$$M = \sum_{m=-s}^s c_m^\dagger \sigma^z c_m. \quad (18)$$

193 In Figure 1(a), we have plotted the Binder cumulant, given by

$$U_4 = 1 - \frac{\langle M^4 \rangle}{3 \langle M^2 \rangle^2}, \quad (19)$$

194 and we see a crossing in the vicinity of **0.20 – 0.21**, that drifts to larger couplings with larger  
195  $N = 2s + 1$ . With this evidence of there being a quantum phase transition, we can find further  
196 evidence that the phase transition is in the Ising universality class by assuming that  $\Delta_\sigma$  is equal  
197 to **0.518**, as is known for the universality class [23], and checking the the magnetization data,  
198 as seen in Figure 1(b). Here we see a good crossing for  $N = 10, 12, 14$ , which is consistent  
199 with the choice of  $\Delta_\sigma$ . The crossing is at a larger  $h$  than the Binder cumulant crossing, that  
200 is because the Binder cumulant suffers from larger finite size effects. Similar finite size effects  
201 have also been observed in the two-layer model [3].

202 To see that the data is consistent with both  $\eta (= 2\Delta_\sigma - 1)$  and  $\nu (= 1/(3 - \Delta_\epsilon))$ , critical ex-  
203 ponents in the 3D Ising universality class, we have performed a data collapse to a universal scal-  
204 ing function, assuming that  $\langle M^2 \rangle / (\sqrt{N})^{4-2\Delta_\sigma}$  has a functional form of  $f_0 + f_1 x + f_2 x^2 + f_3 x^3$ ,  
205 where  $x = (h - h_c) (\sqrt{N})^{3-\Delta_\epsilon}$ . When we fix  $\Delta_\sigma = 0.518$  and  $\Delta_\epsilon = 1.41$  and leave the other  
206 five parameters free, we get a good fit for the data  $N = 10, 12, 14$ , with  $\chi^2 = 1.305$  and an  
207 estimate for the critical coupling of  $h_c = 0.2129(8)$ , as seen in Figure 1(c). If instead we fix  
208  $h = 0.21$ , as suggested by the Binder ratio, and leave six parameters including the critical  
209 exponents free, the fitting gives us  $\Delta_\sigma = 0.49(2)$  and  $\Delta_\epsilon = 1.28(6)$ , values consistent with  
210 Ising universality.

### 211 3.3 Dimensionless two-point correlator

212 To take the advantage of fuzzy sphere regularization, below we compute CFT dimensionless  
213 two-point correlators on a sphere [9] at equal time,

$$\begin{aligned} G_{\phi\phi}(\theta) &= \langle \phi(\theta = \varphi = 0) \phi(\theta, \varphi = 0) \rangle \\ &= \frac{1}{(2 \sin(\theta/2))^{2\Delta_\phi}}, \end{aligned} \quad (20)$$

214 where  $\phi$  is a CFT primary operator, and  $(\theta, \varphi)$  are the spherical coordinates specifying the  
215 positions of the two operators. We mainly focus on the lowest  $\mathbb{Z}_2$ -odd primary  $\sigma$ , which can  
216 be well approximated by the UV operator  $n^z$  [8, 9], up to a non-universal normalization (say  
217  $\sqrt{A}$ ) and higher order corrections  $O(1/\sqrt{N})$  from operators with higher scaling dimensions.  
218 So we can first compute the equal-time two-point correlator,

$$\begin{aligned} f(\theta) &= \langle n^z(\theta = \varphi = 0) n^z(\theta, \varphi = 0) \rangle \\ &= \sum_{l=0}^{2s} \bar{Y}_{l,m=0}(\theta, 0) Y_{l,m=0}(0, 0) \langle n_{l,0}^z n_{l,0}^z \rangle, \end{aligned} \quad (21)$$

219 and then

$$G_{\sigma\sigma}(\theta) = A f(\theta) + O(1/\sqrt{N}), \quad (22)$$

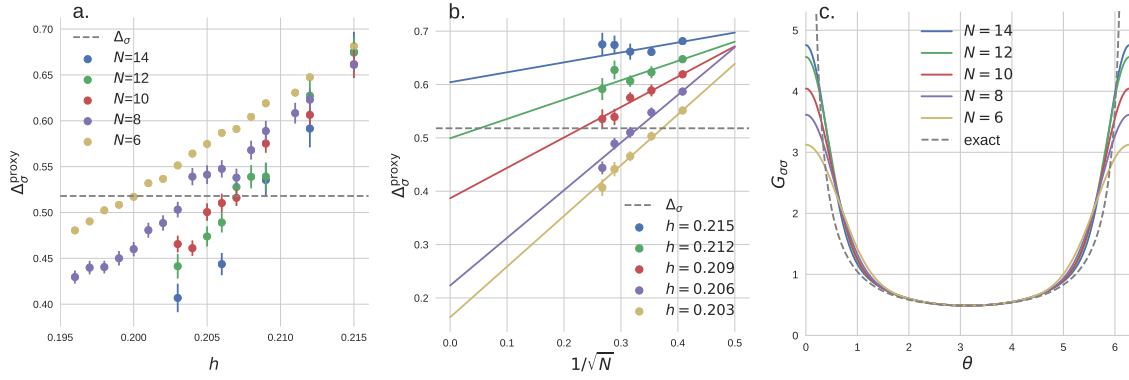

Figure 2: Data from CFT dimensionless two-point correlators. (a) Values of  $\Delta_\sigma^{\text{proxy}}$  from  $G_{\sigma\sigma}$  using the equal-time correlators. The crossing of the  $\Delta_\sigma^{\text{proxy}}$  values through the  $\Delta_\sigma = 0.518$  critical exponent value occurs at larger  $h$ -values as  $N$  increases, consistent with the finite-size-scaling drift that was observed earlier. (b) Extrapolation to infinite lattice size  $\Delta_\sigma$  from  $G_{\sigma\sigma}$  correlation functions for different values of  $h$  and  $N = 6, 8, 10, 12, 14$ . Linear fits suggest that, from this dataset,  $h = 0.212$  is closest to criticality. (c) Plotting of the angle-dependence of the  $G_{\sigma\sigma}$  correlator with data from  $N = 6, 8, 10, 12, 14$  at  $h = 0.212$ .

220 where  $A$  is a nonuniversal number. Because we have an explicit expression for  $f$ , we know  
 221 the exact values for  $f(\theta = \pi)$  and  $f''(\theta)|_{\theta=\pi}$ , where the derivatives are taken in  $\theta$ . Then by  
 222 assuming that  $G_{\sigma\sigma}$  has the critical scaling form of (20), we can solve the following system,

$$\begin{aligned}
 Af(\pi) &= 1/(2 \sin(\pi/2))^{2\Delta_\sigma^{\text{proxy}}} \\
 Af''(\theta)|_{\theta=\pi} &= \frac{\partial^2}{\partial \theta^2} \left( 1/(2 \sin(\theta/2))^{2\Delta_\sigma^{\text{proxy}}} \right) \Big|_{\theta=\pi},
 \end{aligned}
 \tag{23}$$

223  $\Delta_\sigma^{\text{proxy}}$  is a number that will extrapolate to the universal  $\Delta_\sigma$  at the critical point as  $N \rightarrow \infty$ .  
 224 Second derivatives are used for the second equation in (23) because the first derivatives in  $\theta$   
 225 are zero for both  $f$  and critical  $G_{\phi\phi}$  at  $\theta = \pi$ .

226 Figure 2(a) shows the extracted  $\Delta_\sigma^{\text{proxy}}$  values for different values of  $h$  in the vicinity of  
 227 the  $h_c$  determined by finite-size-scaling. Here we see that the  $\Delta_\sigma^{\text{proxy}}$  indeed crosses through  
 228 the 3D Ising  $\Delta_\sigma = 0.518$  value in this region, and furthermore we see that the  $h$  at which this  
 229 crossing occurs increases with system size  $N$ , which is consistent with the drift that we saw in  
 230 the finite-size-scaling. Moreover, the drift appears to be slowing with increasing  $N$ , another  
 231 consistency with finite-size scaling.

232 We can see more consistencies with finite-size-scaling from the results in Figure 2(b), which  
 233 linearly extrapolate the values of  $\Delta_\sigma^{\text{proxy}}$  as  $N \rightarrow \infty$  for different values of  $h$ . Here we see that  
 234 for the infinite  $N$  extrapolation, the  $h = 0.212$  data is closest to the critical  $\Delta_\sigma$ , which is  
 235 consistent with the earlier universal scaling fit of  $h_c = 0.2129(8)$ . We use this  $h = 0.212$  data  
 236 to show the calculation of  $G_{\sigma\sigma}(\theta)$  as a function of  $\theta$  for QMC data at  $N = 6, 8, 10, 12, 14$  and  
 237 how it approaches the exact expression as  $N$  increases. The QMC data-derived expressions for  
 238  $G_{\sigma\sigma}(\theta)$  are given in Figure 2(c) and are rescaled so that they are equal to the exact expression  
 239 of  $G_{\sigma\sigma}(\theta = \pi)$ .

### 240 3.4 Energy gaps and state-operator correspondence

241 Next we turn to the state-operator correspondence [4, 5] on the sphere, namely, the scaling  
242 dimensions  $\Delta_n$  are related to energy gaps by

$$\delta E_n = E_n - E_0 = \frac{v}{R} \Delta_n, \quad (24)$$

243 where  $R$  is the radius of the sphere and  $v$  is the model-dependent velocity of light.

244 While we are unable to get the full low lying energy spectrum directly using QMC, we  
245 are able to obtain energy gaps for the lowest lying states in each symmetry quantum number  
246 sector by using time-displaced correlation functions (see Appendix B). For an operator  $O_S$  with  
247 the quantum number  $S$ , we have:

$$\langle O_S(\tau) O_S(0) \rangle = \sum_n a_n^2 e^{-\tau(E_{S,n} - E_0)}, \quad (25)$$

248 where  $E_0$  is the ground state energy,  $E_{S,n}$  represents the energies of eigenstates  $|\psi_n\rangle$  in the  
249 quantum number sector  $S$ ,  $a_n$  is an operator  $O_S$  and state  $|\psi_n\rangle$  dependent non-universal factor.  
250 At long time  $\tau \gg 1$ , the lowest energy will dominate and can be extracted by fitting the  
251 exponential decay.

252 In the data that follows, we will use density operators  $n_{l,m}^i$  to measure energy gaps in  
253 different quantum number sectors. Specifically,

- 254 1)  $n_{l,m}^z$  can measure gaps in the  $\mathbb{Z}_2$ -odd, parity-even, and angular momentum (i.e. Lorentz  
255 spin)  $l$  sector;
- 256 2)  $n_{l,m}^x$  can measure gaps in the  $\mathbb{Z}_2$ -even, parity-even, and angular momentum  $l$  sector;
- 257 3)  $n_{l,m}^0$  can measure gaps in the  $\mathbb{Z}_2$ -even, parity-odd, and angular momentum  $l$  sector.

258 Figure 3 shows QMC data at the critical point  $h = 0.212$ . The energy gaps are scaled such  
259 that the gap measured from  $n_{l=2,m=0}^0$  is rescaled to 4, the scaling dimension of the lowest  
260 parity-odd descendent of the energy-momentum tensor,  $\Delta_{\epsilon_{\nu\rho\eta}\partial_\rho T_{\mu\nu}}$ . In doing so, we find the  
261 gaps measured from other operators to be consistent with the scaling dimensions of primary  
262 and descendant operators of the 3D Ising CFT. The density operator ( $n_{l=2,m=0}^x$ ) we measured  
263 does not seem to have an overlap with the state of stress tensor (with  $\Delta_{T_{\mu\nu}} = 3$ ). Instead it  
264 gives the level-2 descendant of  $\epsilon$  primary, i.e.,  $\partial_\mu \partial_\nu \epsilon$ .

## 265 4 Conclusions

266 We have introduced a model that is amenable to using sign-problem free quantum Monte  
267 Carlo to simulate the (2+1)- $D$  transverse Ising model on a fuzzy sphere. Through finite-size  
268 scaling we have found data consistent with the model's phase transition being in the 3D Ising  
269 universality class, and we also have shown that we can recover the same critical exponents  
270 from the model's energy spectra, which is evidence of emergent conformal symmetry.

271 While these calculations are not competitive with ED and DMRG for small lattices, this  
272 work opens the door to larger scale calculations for models where there are too many degrees  
273 of freedom to make ED/DMRG calculations infeasible, or for when large sizes are desired for  
274 more accurate determination of critical exponents. One interesting target is the critical gauge  
275 theories proposed in Ref. [10].

Figure 3: Comparison between 3D Ising CFT data and rescaled energy gaps for  $N = 8$  and  $h = 0.212$  measured by density operators. The energy gaps are rescaled by the factor that makes the lowest  $\mathbb{Z}_2$ -even, parity-odd gap at  $l = 2$  equal to the lowest parity-odd descendent of the energy-momentum tensor, **4.0**.

## 276 Acknowledgements

277 We thank Chao Han and Zheng Zhou for stimulating discussions.

## 290 A Order Parameter

291 The Ising order parameter is  $n^z$ , and for QMC simulations we measure the two-point correla-  
 292 tion function,

$$\begin{aligned}
 \langle n^z(\theta, \varphi) n^z(\theta', \varphi') \rangle &= \sum_{l,m,l',m'} \langle n_{l,m}^z n_{l',m'}^z \rangle Y_l^m(\theta, \varphi) Y_{l'}^{m'}(\theta', \varphi') \\
 &= \sum_{l,m} (-1)^m \langle n_{l,0}^z n_{l,0}^z \rangle Y_l^m(\theta, \varphi) Y_l^{-m}(\theta', \varphi'). \quad (\text{A.1})
 \end{aligned}$$

293 The last equation comes from the conservation of angular momentum,

$$\begin{aligned}\langle n_{l,m}^z n_{l',m'}^z \rangle &= \begin{pmatrix} l & l' & 0 \\ m & m' & 0 \end{pmatrix} O_l \\ &= \delta_{l,l'} \delta_{m,-m'} \begin{pmatrix} l & l & 0 \\ m & -m & 0 \end{pmatrix} \langle n_{l,0}^z n_{l,0}^z \rangle / \begin{pmatrix} l & l & 0 \\ 0 & 0 & 0 \end{pmatrix} \\ &= (-1)^m \delta_{l,l'} \delta_{m,-m'} \langle n_{l,0}^z n_{l,0}^z \rangle.\end{aligned}\quad (\text{A.2})$$

294 Therefore, we need to evaluate  $\langle n_{l,0}^z n_{l,0}^z \rangle$  for each  $l$ . To do the finite-size-scaling, we cal-  
295 culate the order parameter  $\langle M^2 \rangle$ , with  $M = \int d\Omega n^z(\theta, \varphi)$ ,

$$\begin{aligned}\langle M^2 \rangle &= \int d\Omega d\Omega' \langle n^z(\theta, \varphi) n^z(\theta', \varphi') \rangle \\ &= \sum_{l,m} (-1)^m \langle n_{l,0}^z n_{l,0}^z \rangle \int d\Omega d\Omega' Y_l^m(\theta, \varphi) Y_l^{-m}(\theta', \varphi') \\ &= 4\pi \langle n_{0,0}^z n_{0,0}^z \rangle\end{aligned}\quad (\text{A.3})$$

296 The last equation comes from  $\int d\Omega Y_l^m(\theta, \varphi) = \sqrt{4\pi} \delta_{l,0} \delta_{m,0}$ . Using Wigner-3j identities, we  
297 find that,

$$\begin{aligned}n_{0,0}^z &= (2s+1) \sqrt{\frac{1}{4\pi}} \sum_{m_1=-s}^s (-1)^{3s+m_1} \begin{pmatrix} s & 0 & s \\ -m_1 & 0 & m_1 \end{pmatrix} \begin{pmatrix} s & 0 & s \\ -s & 0 & s \end{pmatrix} c_{m_1}^\dagger \sigma^z c_{m_1} \\ &= \sqrt{\frac{1}{4\pi}} \sum_{m_1=-s}^s c_{m_1}^\dagger \sigma^z c_{m_1}.\end{aligned}\quad (\text{A.4})$$

298 Therefore, the order parameter  $M^2$  is

$$\langle M^2 \rangle = \sum_{m_1, m_2=-s}^s \langle (c_{m_1}^\dagger \sigma^z c_{m_1}) (c_{m_2}^\dagger \sigma^z c_{m_2}) \rangle.\quad (\text{A.5})$$

## 299 B Extracting Energy Gaps

300 In projector QMC, we are able to get the energy gap between the first excited state in symmetry  
301 sector  $S$  and the ground state in the following way. Assuming a trial wavefunction,  $|\psi_0\rangle$ , an  
302 operator that creates overlap between the states in symmetry sector  $S$  and the ground state,  
303  $O_S$ , and a complete set of states  $\sum_n |n\rangle \langle n|$ , where  $|n\rangle$  is an eigenstate with energy eigenvalue  
304  $E_n$ , we have that

$$\begin{aligned}\langle O_S(\tau) O_S(0) \rangle &= \frac{\langle \psi_0 | e^{-(\beta-\tau)H} O_S e^{-\tau H} O_S | \psi_0 \rangle}{\langle \psi_0 | \psi_0 \rangle} \\ &= \sum_n \frac{\langle \psi_0 | e^{-(\beta-\tau)H} O_S | n \rangle \langle n | e^{-\tau H} O_S | \psi_0 \rangle}{\langle \psi_0 | \psi_0 \rangle} \\ &= \sum_n \frac{\langle \psi_0 | O_S | n \rangle \langle n | O_S | \psi_0 \rangle}{\langle \psi_0 | \psi_0 \rangle} e^{-\beta E_0} e^{-\tau(E_n - E_0)}.\end{aligned}\quad (\text{B.1})$$

305 This term has contributions from all eigenstates that have the symmetry  $S$ . The higher energy  
306 states will have gaps that will be suppressed relative to the smallest energy gap, and so we can  
307 approximate

$$\langle O_S(\tau) O_S(0) \rangle = C_1 e^{-\tau(E_S^0 - E_0)} + C_2 e^{-\tau(E_S^1 - E_0)},\quad (\text{B.2})$$

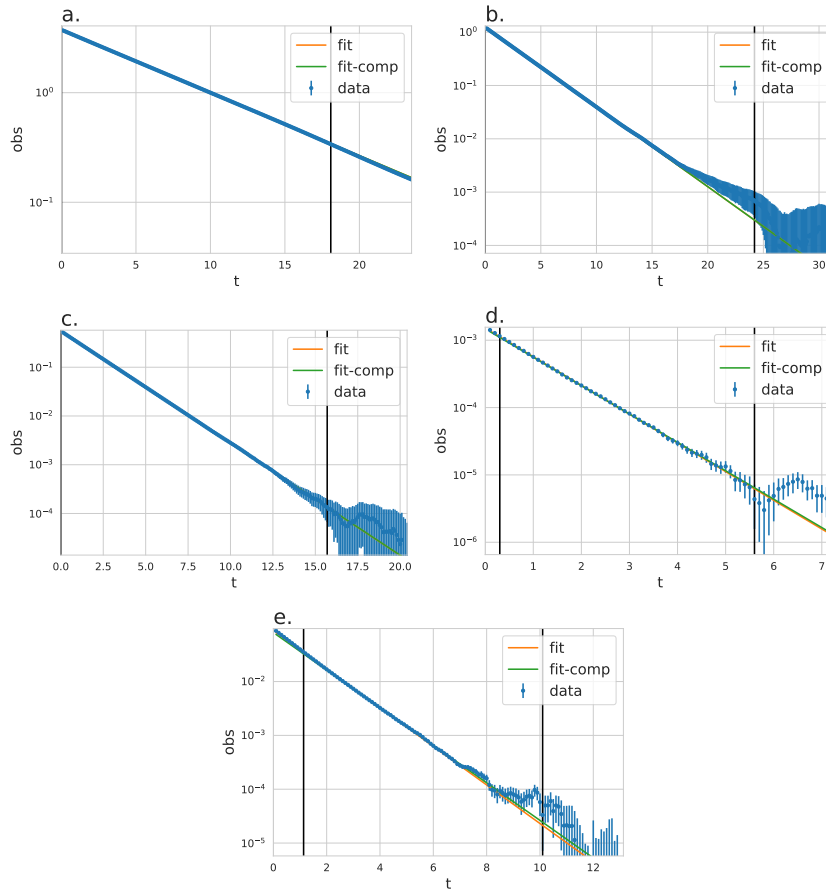

Figure 4: Fits to one exponential using semilog plots. The vertical lines show the locations of the endpoint and startpoints for the data. Plots (a), (b), and (c) show the data from  $n_{0,0}^z$ ,  $n_{1,0}^z$ , and  $n_{2,0}^z$ , respectively. Plot (d) shows the data from  $n_{2,0}^0$  and plot (e) shows the data from  $n_{2,0}^x$ .

308 where  $E_S^0$  and  $E_S^1$  are the lowest energy and second lowest energy corresponding to states in  
 309 symmetry sector  $S$ , respectively.

310 In practice, we found that in order to extract  $E_S^0$ , sometimes a fit to the two exponentials  
 311 with prefactors  $C_1$  and  $C_2$  in (5) is necessary, but sometimes a fit to a single exponential (which  
 312 assumes  $C_2 = 0$ ) is more appropriate. The procedure for fitting to one versus two exponentials  
 313 involves the following steps:

- 314 1. Find the  $\tau$  interval where the data is distinguishable from zero according to error bars.  
 315 The largest time in this interval is the initial “endpoint” guess.
- 316 2. Initially guess that the “midpoint” in time—where one exponential versus the other ex-  
 317ponential dominates—is **30%** of the full time interval.
- 318 3. Test a fit to a single exponential—if the initial data point is smaller than the  $t = 0$  value  
 319 for the fitted function, gradually adjust the midpoint and endpoint guesses down until  
 320 this is not the case.
- 321 4. If the initial data point is still within errors of the  $t = 0$  value for the single-exponential  
 322 fitted function, fit the data to a single exponential. If not move on to a two-exponential  
 323 fit and then revise the midpoint guess such that the value of the larger exponential in  
 324 the fit is negligible compared to that of the smaller exponential at the midpoint.

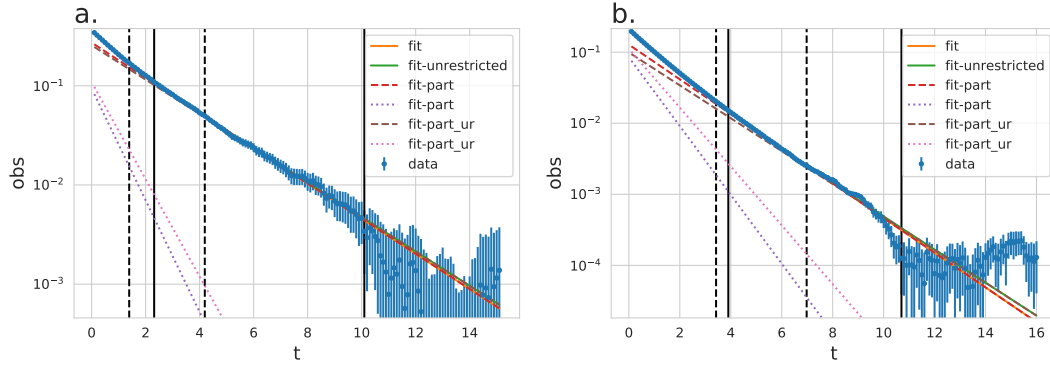

Figure 5: Fits to two exponentials using semilog plots. The vertical solid lines show the locations of the endpoint and midpoint for a restricted fit—where the  $C_1$  exponential and the  $C_2$  exponential are fitted separately but iteratively using information from previous results to arrive at a final answer. The dashed lines give an interval of midpoints that were tested in order to estimate the error bar. The solid diagonal lines give the two-exponential restricted and unrestricted fits (“fit” and “fit-unrestricted”). The dashed diagonal lines are fits for each of the two exponentials, both for restricted (“fit-part”) and unrestricted (“fit-part\_ur”) fits. Plot (a) shows the data from  $n_{0,0}^x$ , and plot (b) shows the data from  $n_{1,0}^x$ .

325 For the operators  $n_{1,0}^z$ ,  $n_{2,0}^0$ , and  $n_{2,0}^x$ , the fit to a single exponential ends up being more ap-  
 326 propriate. Figure 4 shows the fits to a single exponential (in the cases of  $n_{2,0}^2$  and  $n_{2,0}^x$ , we  
 327 chose a single exponential because there was very little small  $\tau$  data to fit to a higher expo-  
 328 nential). However, the  $n_{0,0}^x$ ,  $n_{1,0}^x$  observables require two exponentials. Figure 5 shows the  
 329 two exponential fits for these operators at coupling  $h = 0.212$  and  $s = 3.5$ .

330 For the two-exponential fits, we first use the midpoint data to iteratively fit one exponential  
 331 at a time: midpoint to endpoint is the fit for the lower energy and then the startpoint to the  
 332 midpoint is the fit for the higher energy. We alternate fitting one exponential versus the other  
 333 while fixing the parameters of the nonfitted exponential according to the previous fit. This  
 334 gives us the “restricted” fit listed as “fit” in Figure 5. We then use these fitted energy values as  
 335 initial guesses for an “unrestricted” fit that fits both exponentials at once. This gives the “fit-  
 336 unrestricted” in Figure 5. The value of the energy estimate is the mean of these restricted and  
 337 unrestricted fit energies. Finally, we obtain error bars by performing fits to a single exponential  
 338 for the smaller energy from a midpoint to the endpoint, where we calculate the midpoint as

$$\tau = -\frac{1}{(E_s^1 - E_s^0) \ln\left(\frac{\epsilon C_1}{C_2}\right)}, \quad (\text{B.3})$$

339 where  $\epsilon$  is a small number representing the time when the value of  $C_2 e^{-\tau(E_s^1 - E_0)}$  is  $\epsilon$  times  
 340  $C_1 e^{-\tau(E_s^0 - E_0)}$ . We take a range of  $\epsilon \in \{0.01, 0.1\}$  to fit  $E_s^0$  and use this range of  $E_s^0$  values to  
 341 estimate the error for the energy. The boundaries of this range of midpoints are given by the  
 342 dashed vertical lines in Figure 5.

### 343 C Finite size scaling of energy gaps

344 Because the QMC model studied has an additional  $SU(2)$ -layer symmetry, one check to make  
 345 is whether the degrees of freedom in the layer  $SU(2)$  non-singlet representations are gapped

Figure 6: Data showing the energy gaps obtained from the  $SU(2)$  singlet operators as a function of  $1/\sqrt{N}$  for  $N = 8, 10, 14$ . This data is in the vicinity of the critical point at  $V_1 = 0.1, V_0 = 0.5564, h = 0.2$ . The gaps decrease with system size, as expected. Extrapolations are shown for the  $\mathbb{Z}_2$ -odd sector, but not the even sector since the error bars are so large.

Figure 7: Data showing the energy gaps obtained from operators of the form  $\sigma^i \tau^z$  as a function of  $1/\sqrt{N}$  for  $N = 8, 10, 14$  (operators of the form  $\sigma^i \tau^{x,y}$  would give the same states, making this the  $SU(2)$  triplet symmetry class). This data is in the vicinity of the critical point at  $V_1 = 0.1, V_0 = 0.5564, h = 0.2$ . These energies appear to be gapped out.

346 at the phase transition. All the operators in the Hamiltonian are of the form  $\sigma^i \tau^0$ , which are  
347 the singlets of the layer  $SU(2)$  symmetry. Figure 6 shows the energy gaps obtained from these  
348 operators as a function of  $1/\sqrt{N}$  at  $h = 0.2$ , which is in the vicinity of the critical point. All  
349 gaps are decreasing with system size and the gaps for the  $\mathbb{Z}_2$ -odd sector seem to be trending  
350 linearly towards the origin, as required by the state-operator correspondence. The  $\mathbb{Z}_2$ -even  
351 sector gaps are also decreasing with increasing system size, but they have larger error bars  
352 due to interference with other higher energy descendants in their spectrum, and the details of  
353 their fits are given in Appendix B of the Supplementary Material. On the other hand, the layer  
354  $SU(2)$  non-singlet, e.g., layer triplet gaps should be finite in the thermodynamic limit. Figure  
355 7 shows layer triplet energy gaps measured by  $\sigma^i \tau^{x,y,z}$ , as a function of  $1/\sqrt{N}$ , and from here  
356 we see that these excitations appear to be gapped.
