1 Abstract

2 The homeostasis of epithelial tissue relies on a balance between the self-renewal of stem
3 cell populations, cellular differentiation, and loss. Although this balance needs to be
4 tightly regulated to avoid pathologies, such as tumor growth, the regulatory mecha-
5 nisms, both cell-intrinsic and collective, which ensure tissue steady-state are still poorly
6 understood. Here, we develop a computational model that incorporates basic assump-
7 tions of stem cell renewal into distinct populations and mechanical interactions between
8 cells. We find that the model generates unexpected dynamic features: stem cells repel
9 each other in the bulk tissue and are thus found rather isolated, as in a number of in
10 vivo contexts. By mapping the system onto a gas of passive Brownian particles with ef-
11 fective repulsive interactions, that arise from the generated flows of differentiated cells,
12 we show that we can quantitatively describe such stem cell distribution in tissues. The
13 interaction potential between a pair of stem cells decays exponentially with a character-
14 istic length that spans several cell sizes, corresponding to the volume of cells generated
15 per stem cell division. Our findings may help understanding the dynamics of normal and
16 cancerous epithelial tissues.

17 1 Introduction

18 Tissue renewal through cell division to balance the constant loss of cells is a hallmark of life
19 in multicellular organisms. It is widely accepted that for most tissue types, stem cells (SC)
20 play a key role in this complex process [1, 2]. Stem cells have the potential to proliferate and
21 self renew over long timescales, continuously generating various types of differentiated cells
22 required for physiological tissue function. Such tissue maintenance via small populations of
23 stem cells requires fine-tuned fate choices to ensure not only a constant and well-defined ratio
24 of cellular types, but also stable tissue size and overall cellular numbers.

25 Equally important, however, is a homogeneous positioning of stem cells across the tissue,
26 such that lost cells can quickly be replenished. If all stem cells were to segregate from progeny,
27 tissue function and maintenance could be compromised. Indeed, in a lattice model without
28 mechanical interactions, proliferating and non-proliferating cells have been shown to require
29 reversible differentiation in a manner dependent on relative local cell numbers to avoid non-
30 homeostatic behavior, such as phase separation of cell types [3]. Other types of fate control that
31 have been recently explored theoretically and experimentally are an effective fate determinant
32 field of a diffusible chemical. It is homogeneously supplied but consumed by stem cells, thus,
33 providing a biochemical negative-feedback mechanism for stem cell density, which can also
34 reproduce homogeneous distribution of stem cells within the tissue [4].

35 In recent years, mechanical forces have been shown to be crucial regulators for tissue
36 growth and homeostasis. A key concept is the *homeostatic pressure*, which is the pressure at
37 which cellular division and apoptosis are balanced, under the generic assumption that these
38 processes depend on mechanical forces. Based on this concept, competition between different
39 tissues [5], tissue fluidization [6], negative bulk homeostatic pressure [7], interface dynamics
40 during competition [8–10], and the evolution of tissue [11] could be explained. However,
41 these studies always considered situations without the possibility of conversion between cel-
42 lular types and change in self-renewal potential, which is by definition key to understand stem
43 cell dynamics in tissues. This raises the question of whether purely mechanical interactions,
44 which must occur in any confluent tissue with cell renewal and loss, could be a factor in the
45 regulation of stem cell dynamics and positioning.

46 Here, we study the interaction and distribution of stem cells in self-renewing tissues in
47 the presence of mechanical interactions only. As a minimal hierarchical scheme of tissues
48 with stem and differentiated cells (Fig. 1a), we take a classical model [12], where stem cells
49 (SC) asymmetrically divide into a stem and a transient amplifying (TA) cell. The TA cells
50 can undergo a number N_{TA} of symmetric divisions before terminally differentiating into non-
51 proliferative cells (TD). Although this is an oversimplified picture [13], we show that it already
52 gives rise to complex dynamics and provides a computational framework which can be readily
53 generalized to more realistic stochastic models of cell differentiation. For instance effects of
54 the stem cell environment, the so called niche, on fate decisions [14, 15] or self-controlled fate
55 decisions such as in "open niche" [16], where all cells have the same differentiation potential.
56 Implementing the renewal scheme into the two particle growth model [17] (sec. 2 and App. B),
57 we find that the resulting tissue is characterized by well separated SCs surrounded by a small
58 cloud of TA cells in a sea of TD cells in two (see Fig. 1b), and three dimensions (see sec. 6). The
59 cause of the homogeneous distribution of stem cells in the tissue on larger distances lies in the
60 of outflux of cells from the stem cells, and short-range mechanical interactions. Surprisingly,
61 we find that this repulsion and distribution of SC in the tissue can be effectively described by
62 a simple thermodynamic picture with SCs behaving like soft repulsive colloids in a thermal
63 bath. The length scale of the soft repulsive potential is set by the volume of cells generated
64 per stem cell division.

65 In section 3, we first discuss the dynamics of single stem cells to determine the length
66 scale of the interaction, and to study how the cloud of their progeny around them impacts
67 their movements. Subsequently, in section 4, we study the dynamics of SC pairs. From their
68 distance distribution function, we infer the amplitude of the effective repulsive potential that
69 is mediated by the outward flow of differentiated cells that they each produce. In section 5,
70 we show that the distribution of stem cells in a bulk tissue can be described by this effective
71 pair interaction. In three dimensions, we find that the repulsive interaction of stem cells is
72 also preserved (see sec. 6). Last, we demonstrate independence of the homeostatic pressure
73 controlled division mechanism, by replacing it with a stochastic one, in section 7. This shows
74 that our results are primarily driven by mechanical interactions and proliferation generated
75 outflow of cells.

76 2 Simulation model

77 Each cell in the simulation model consists of two particles, which interact via a repulsive force
78 to model growth. When the particle distance reaches a size threshold, a cell divides and two
79 new particles are placed at random at very short distance next to the old ones. Particles of
80 different cells interact via an attractive and a repulsive force, to model adhesion and volume
81 exclusion, respectively. The length R_{pp} , up to which inter-cellular interactions are present,

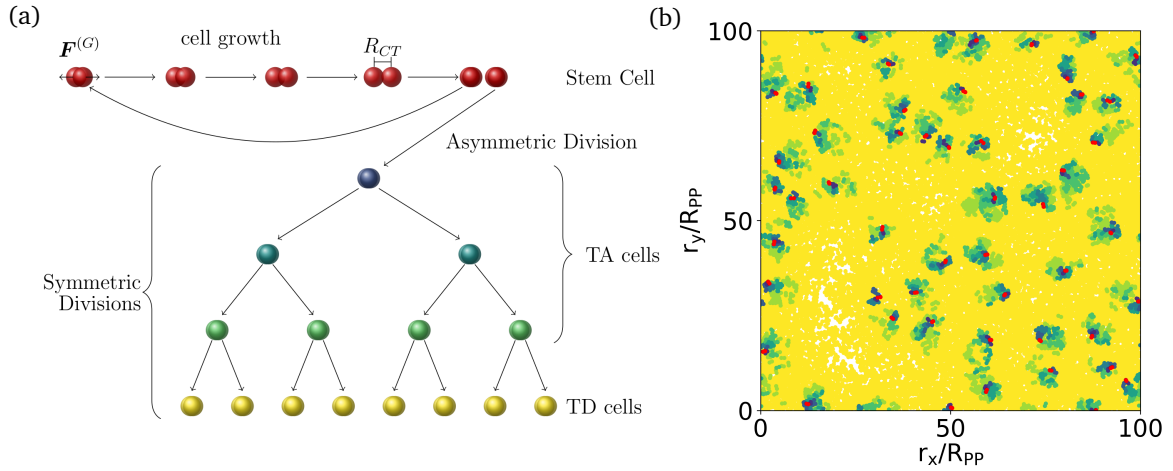

Figure 1: **Stem cell (SC) division and differentiation scheme leads to well-separated SC arrangement.** (a) Schematic illustration of growth, division, and differentiation implemented in the two-particle growth model. SCs grow by an active growth force $F^{(G)}$ and divide when the two particles of a cell are separated by a threshold distance R_{ct} . A SC divides always asymmetrically in one SC daughter and one TA daughter cell. TA cells still grow, but their maximal number of divisions are limited. They always divide symmetrically, and in the final step both daughters are TD cells. TA and TD cells are removed with the same, finite apoptosis rate k_a . (b) In bulk simulations, SCs are distributed all over the tissue, and rarely at close distance. Each SC is surrounded by a halo of TA and TD cells. The main mass is made up by non-growing TD cells. The same color scheme as in Fig. 1a is applied with finer gradation for TA cells, which can divide up to five times. The simulation was performed in a squared two-dimensional box with box length $100 R_{pp}$. After equilibration, the average cell density is $\rho \sim 1.58/R_{pp}$, and the snapshot was taken after 25 generations.

82 defines the length scale of our model and depicts the cell size. TA and TD cell removal is
 83 modeled in a stochastic process with fixed rate k_a , which defines the timescale of the model.
 84 Note that the division rate k_d is not fixed and will follow from the other model parameters.
 85 Random and dissipative forces are included by dissipative particle thermostat. Together with
 86 a self-consistent velocity Verlet integrator for the Langevin equations, this enables efficient cal-
 87 culations, correctly accounting for the overdamped dynamics required for tissue simulations,
 88 as discussed in detail in App. D.3. Cells follow a classical differentiation model [12], see
 89 Fig. 1a, and have all identical interaction parameters. Solely stem cells do not die ($k_a = 0$),
 90 and TD cells do not actively grow ($G = 0$) to prevent divisions. All simulations in this work
 91 are initialized with SCs only. More details on the model can be found in App. B and previous
 92 works [7, 8, 10, 11, 17].

93 3 Isolated stem cell

94 To understand the separation of stem cells in bulk tissue, we begin our analysis by studying
 95 the dynamics of a single SC and its offspring. We start with an isolated stem cell and shortly
 96 thereafter find it surrounded by a cloud of progeny that maintains a certain size throughout
 97 the simulation time. (see Fig. 2a).

98 Assuming equal division rates k_d for SC and TA cells and neglecting TA cell loss on average

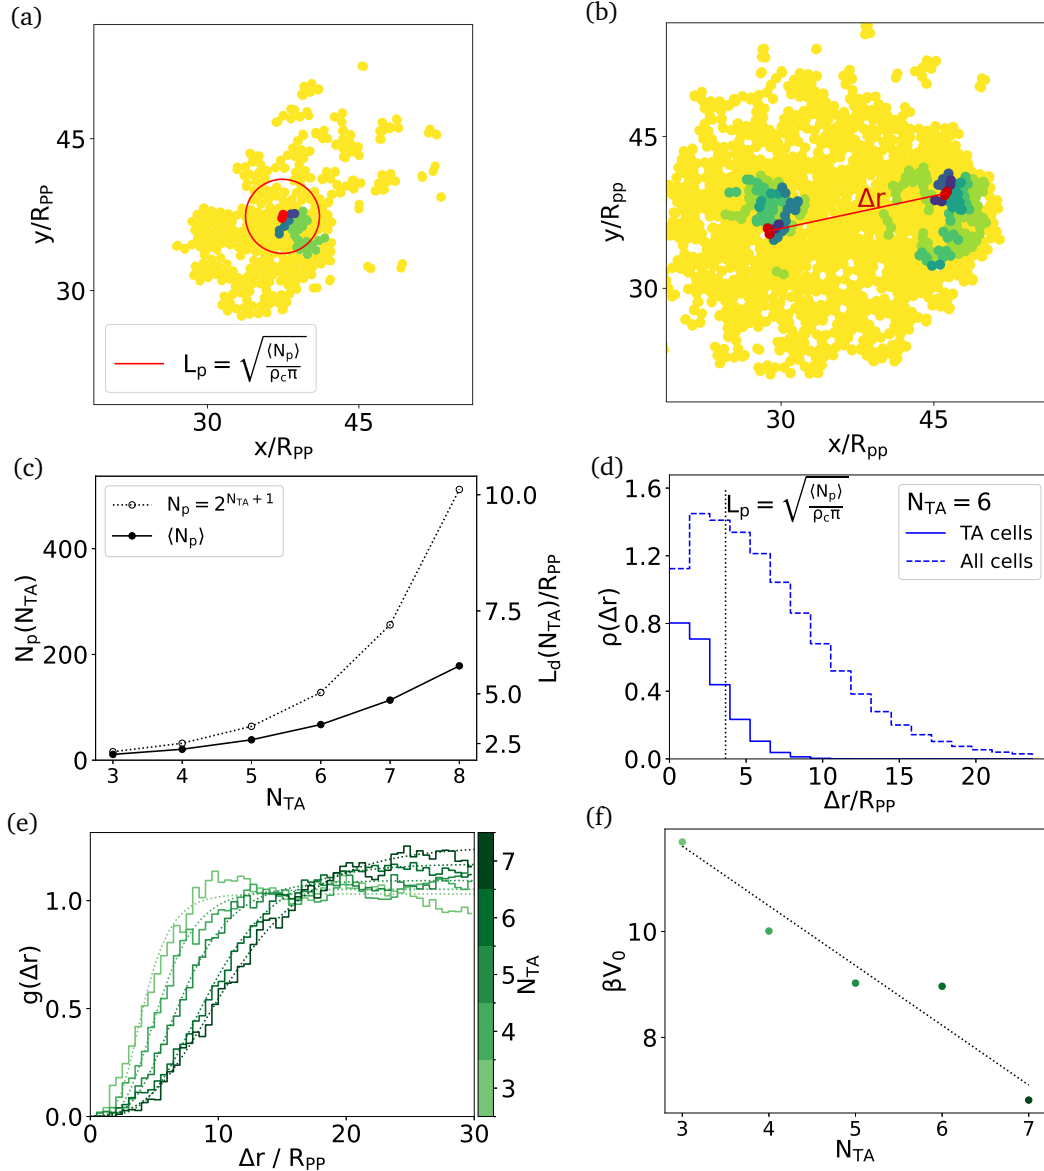

Figure 2: **Interaction parameter determination.** (a) Snapshot of isolated SC and (b) two interacting SCs. (c) Cell number generated in each SC division cycle, i. e. sum of TA cell and latest TD cells, for the upper limit $N_p = 2^{N_{TA}+1}$ (open circles, dotted line) and measured from simulation by averaging over time $\langle N_p \rangle$ (filled circles, solid line) as function of N_{TA} . The latter is used to determine the characteristic progeny distance L_p , which is used on the right y-axis label. (d) Cell density of TA (solid line) and all daughter cells (dashed line) around SC, where L_p derived from average measured progeny number N_p is marked by dotted line, for $N_{TA} = 6$. (e) pair correlation $g(\Delta r)$ as function of SC distance Δr for a pair of SCs. N_{TA} is coded in color. Fit shows interaction via repulsive potential and obtained interaction strength βV_0 is shown in (f) as a function of N_{TA} . Multiple independent long simulation runs of these systems for each N_{TA} are used to determine the interaction parameters. Simulations are initialized from a single SC (a, c, d) and two SCs in contact (b, e, f) and averages are taken in steady state, i. e. after reasonably long time after initialization.

99 $2^{N_{TA}}$ growing cells are present at a time, with N_{TA} the maximum allowed number of TA cell
 100 division cycles. Further, $2^{N_{TA}}$ TD cells are produced in each cycle. Thus, each stem cell

101 division can produce at most $2^{N_{TA}+1}$ progeny. However, due to the stochastic loss rate k_a of TA
 102 and TD cells in our model (which can occur either due to apoptosis in monolayers, or out-of-
 103 plane delamination in multilayered tissues such as the epidermis) we arrive at a lower effective
 104 number $\langle N_p \rangle < 2^{N_{TA}+1}$ (see Fig. 2c). On average, the stem cell is thus surrounded by a circular
 105 arrangement of its offspring, with a characteristic length $L_p = \sqrt{\langle N_p \rangle / \rho \pi}$, where ρ denotes
 106 the cell density (see Fig. 2d). Note that k_a is not fixed in our simulation model, but controlled
 107 by pressure. [5, 7, 18] An increase of TA cell generations can thus decrease the proliferation
 108 rate and effective cell number further (see App. C Fig. 7).

109 However, the average hides an important aspect of the dynamics. While in some instances
 110 the SC is indeed in the center of the cell mass, it is also often found at the boundary due to
 111 the stochastic nature of the orientation of asymmetric divisions. When the SC is located at the
 112 boundary, the divisions of the TA cells result in an effective propulsion of the SC and persistent
 113 directed motion (App. D Fig. 8).

114 Correspondingly, the mean squared displacement (MSD) of the stem cell shows a regime
 115 of active motion up to about the lifetime of one generation, and a regime of activity enhanced
 116 long-term diffusion thereafter (see Fig. 4a and App. D Fig. 9). In analogy to active Brownian
 117 particles (ABPs) or Run'n'Tumble particles, the MSD of stem cells can be described in terms of
 118 a translation diffusion coefficient D_t , a characteristic rotational time τ_R , which confirms decor-
 119 relation of the SC motion after about one cell generation, and a propulsion velocity v_0 (see
 120 App. D.1). The fitted values for τ_R are about one half to one apoptosis times and correspond
 121 to the decorrelation of directed motion. For the propulsion velocity we find a maximum for
 122 $N_{TA} = 6$, indicating an optimal population size for sped-up motion.

123 We quantify the active outbursts of SC motion by the displacement distribution of the
 124 stem cell, i. e. the probability that the SC undergoes a given displacement within a fraction
 125 of a generation (*here* $0.2/k_a$ see App. D Fig. 11a). Heavy tails in the distribution display the
 126 persistent motion during outburst. When a stem cell is displaced from the center of mass of
 127 the cell population the heaviness of the tail increases strongly (see App. D Fig. 11b).

128 4 Stem cell interaction

In order to derive an effective pair interaction, we initialize the simulation with two stem
 cells in a large periodic box. Each stem cell generates its own progeny populations, which
 form an aggregate via which stem cells effectively repel each other (see Fig. 2b). Loss of cells
 in the region between stem cells can lead to two separate cell populations, both behaving
 as described in the previous section. In simulations with periodic boundary conditions, they
 eventually collide again and SC rejection can be observed yet again. We quantify the stem cell
 repulsion by measuring the pair correlation function

$$g(r) = \left\langle \sum_{m,n \neq m}^{N_{SC}} \Theta_H(r - r_{mn}(t_i)) \Theta_H(r_{mn}(t_i) - (r + \delta r)) / \Omega(r) \right\rangle$$

129 in an annulus ranging from r to $r + \delta r$, where $\Theta_H(x)$ is the Heaviside function and $r_{mn}(t_i) =$
 130 $|\mathbf{r}_m(t_i) - \mathbf{r}_n(t_i)|$ the stem cell pair distance, measured applying minimum image convention.
 131 The average combines data from different times and independent runs to improve statistics and
 132 the sum runs over pairs of SC. In order to normalize $g(r)$, and to take into account the radial
 133 bin size, we divide by a geometrical scaling constant $\Omega(r) = L_{XY}^2 / [4(N_{SC} - 1)((r + \delta r)^2 - r^2)]$.
 134 The probability to find two SCs at short distances is strongly reduced, and reaches a plateau
 135 at larger distances, where the cell clouds are out of contact again (see Fig. 2e).

136 Next we utilize an analogy to thermal equilibrium to derive an effective repulsive pair
 137 potential $V(r) = V_0 \exp\{-r/L_{rep}\}$ of very soft colloids. The repulsion length L_{rep} is set to the

138 characteristic length L_p of progeny around the SC. In equilibrium, the pair correlation function
 139 follows from Boltzmann statistics

$$G(r) = G_0 \exp \left\{ -\beta V_0 \exp \left\{ -r/L_p \right\} \right\}, \quad (1)$$

140 with $\beta = 1/k_B T_{eff}$ and effective temperature T_{eff} . The prefactor G_0 is obtained from the
 141 normalization condition $\int G(x) dx = 1$. We determine the effective potential strength βV_0
 142 by fitting $G(r)$ to $g(r)$ and find good agreement of this simple model with our data. Results
 143 are shown in Figure 2e+2f. The decrease of βV_0 with N_{TA} corresponds to a softening of the
 144 potential, which could be due to an increasingly asymmetric distribution of TA cells.

145 5 Confluent tissue maintained by stem cells

146 We perform tissue simulations for different N_{TA} , and vary the number of stem cells N_{SC} in
 147 the simulation such that the average total cell density is approximately the same for different
 148 simulations. We compare these tissue simulation with Brownian dynamics (BD) simulations
 149 of thermal colloid particles interacting via the proposed effective repulsion. The interaction
 150 parameters, obtained in section 4, are used without further adaptations. Snapshots for the
 151 mechanical model and the thermal colloid model are shown in Figure 3a and 3b, respectively.

152 Clearly, SCs are well separated, and homogeneously distributed over the system. To quan-
 153 tify this separation, we measure again the pair correlation function for both systems (see
 154 Fig. 3c). The pair correlation function reveals a strong depletion of stem cells from the vicinity
 155 of another on length scales set by the amount of progenitors they generate. Interestingly, we
 156 find that the colloid system (dotted lines) reproduces well the results from the tissue simu-
 157 lations (solid lines) even in confluent tissues. Note that this requires a rather soft colloidal
 158 interaction on length scales much larger than the (stem) cell size.

159 We further quantify the stem cell separation with a cluster analysis. We consider that SCs
 160 which are found at a distance smaller than d belong to the same cluster, and calculate the
 161 cluster size distribution function $\mathcal{N}(n) = p(n) \cdot n$, where $p(n)$ is the probability of a cluster
 162 of n SCs, and average cluster size $\langle n \rangle$. If we take the distance threshold d equal to the cells
 163 interaction range R_{pp} , as commonly done for cluster analysis, we identify close to no clusters
 164 at all ($\mathcal{N}(n=2) = 0.024$ and $\mathcal{N}(n=3) = 0.00014$, for $N_{TA} = 5$). By choosing a larger cutoff
 165 $d = 2L_p$ on the basis of their progeny, we find some small clusters, but still not any large
 166 clusters (see Fig. 3d and App. E Fig. 14), a feature indicative of SC separation, which is also
 167 reproduced in the colloidal systems.

To obtain more insight in the structural dynamics of both systems, we additionally calculate
 the MSD of SC, and the intermediate scattering function

$$S(q, t) = \left\langle \sum_{m=1}^{N_{SC}} \sum_{n=1}^{N_{SC}} e^{i\mathbf{q} \cdot \mathbf{r}_m(t)} e^{-i\mathbf{q} \cdot \mathbf{r}_n(0)} \right\rangle,$$

168 where $\langle \cdot \rangle$ denotes a time average and we calculate the over $S(q, t)$ with wave vector $q = |\mathbf{q}|$
 169 (see Fig. 4b).

170 The MSD of SCs in tissues shows the same superdiffusive behaviour as found for an iso-
 171 lated SC in free space (see Fig. 4a). However, the displacement is reduced in confluent tissue
 172 due to the increased cell density. We find, that this affects mainly the translational diffusion
 173 coefficient and propulsion velocity, while the reorientation remains in the same order of mag-
 174 nitude as for isolated SC (see App.D Fig. 10). The thermal colloid system on the other hand
 175 shows normal diffusion, as should be. Because the Boltzmann description does not provide
 176 any timescales, we use the short-term diffusive limit of colloids and SCs in tissues to fix the

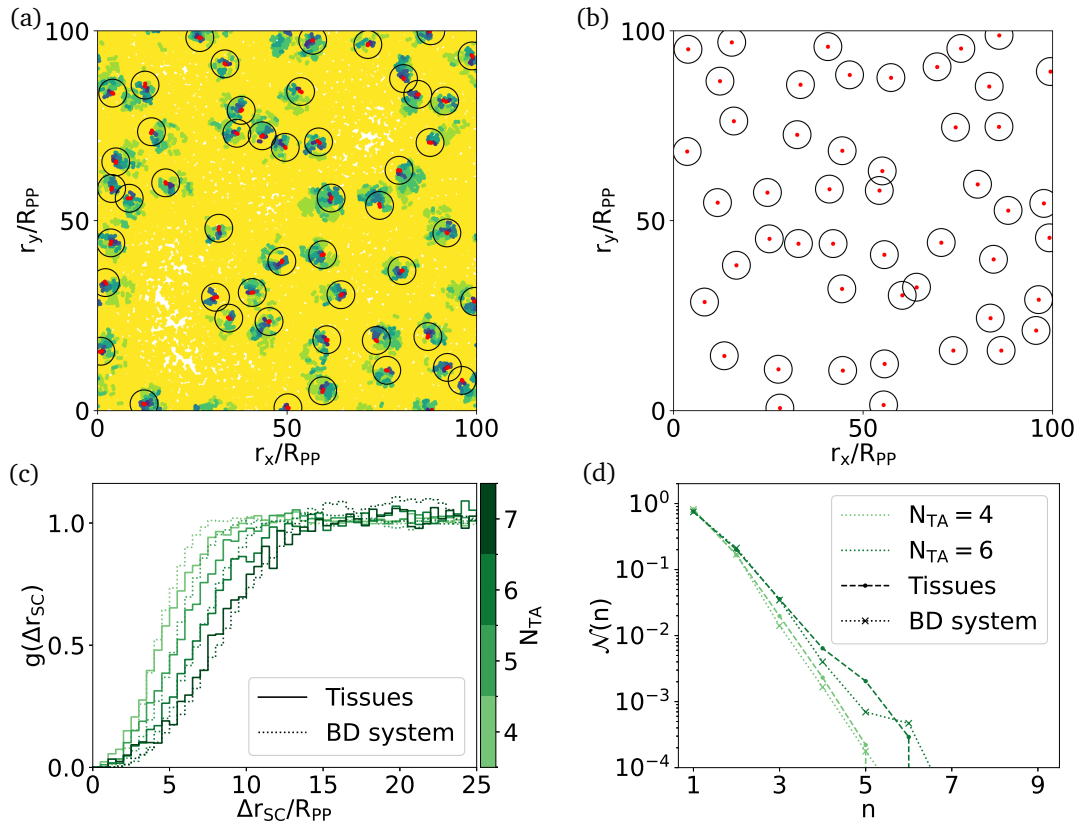

Figure 3: **SC separation in bulk tissue is explained by equilibrium model with simple repulsive interaction.** (a) Snapshot of the tissue simulation for $N_{TA} = 7$ and (b) respective thermal colloid simulation. The characteristic progeny length scale is displayed by circles. (c) The SC and particle pair correlation functions, measured from simulations of the two-particle growth model (solid lines) and thermal colloids, interacting with the assumed repulsive interaction (dotted lines), are shown for color coded N_{TA} . (d) Cluster size distribution function for SCs in tissues (dots, dashed line) and thermal colloids (cross, dotted line) for color coded N_{TA} . Distance threshold for clustering is set to $d = 2L_p$, much larger than the cell size, in order to see any clustering at all. The number of SCs was chosen such that the cell density in all simulations is ~ 1.58 cells/ R_{PP} , and the number of thermal colloids equals the number of SCs. Interaction parameters of colloids were extracted from single and two SC simulations. Note the astonishing agreement between both systems. Simulations are initialized with fixed number of SCs or thermal colloids at regularly spaced distances and averages are taken in steady state, i. e. after reasonably long time after initialization.

177 timescale. The short-term diffusion coefficient can also be calculated from the relaxation of
 178 the intermediate scattering function as $D_{eff} = -\log\{S(q, t)/S(q, 0)\}/(q^2 t)$ in the short time
 179 limit. After aligning the time scale of the thermal colloid system, we find that this effective
 180 diffusion is approximately the same for both systems (see App. E Fig. 15). For large q , D_{eff} is
 181 constant, while for small q , finite-size effects of the simulation area come into play.

182 For zero time lag ($S(q, \Delta t = 0)$), we find a plateau, corresponding to the autocorrelation
 183 term ($n = m$). With a finite time lag, the scattering function starts to decay with q (see Fig. 4b
 184 for $\Delta t = 0.02k_d$). For tissues and colloids, we show the relaxation of small and large structures
 185 in Fig. 4c and Fig. 4d, respectively. Because we match the timescale of both systems for the
 186 short-term diffusion, we find that small structures relax at similar times. Still, SCs in tissue

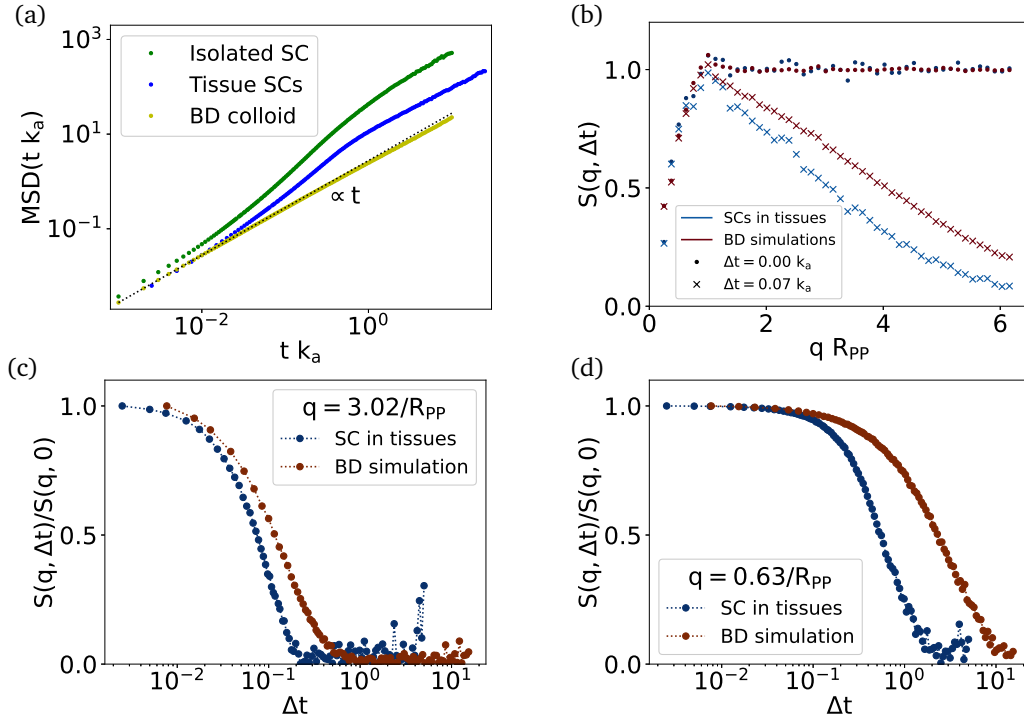

Figure 4: **Dynamics of SC and BD simulations.** (a) Mean squared displacement (MSD) for isolated SC (green) and SCs in tissue (blue), both with $N_{TA} = 4$, and respective thermal colloid system (yellow). In the tissue model, we find superdiffusive SCs. Their displacement gets reduced with increased cell density in confluent tissues. Time scale of thermal colloid system was aligned with the short term diffusion of SC in tissues. (b) Dynamic structure factor (DSF) as function of wavevector for $t = 0$ and $t = 0.07k_a$. Relaxation of the DSF as function of time for (c) small structures ($q = 3.08/R_{pp}$ or $\lambda_q = 2.03R_{pp}$, i. e. twice the cell diameter) and (d) large structures ($q = 0.69/R_{pp}$ or $\lambda_q = 9.11R_{pp}$, i. e. comparable to "weakly" interacting stem cells). Small structures relax at comparable timescale, whereas large structures relax faster in the tissue model due to the superdiffusive behavior of stem cells. Simulations are initialized with fixed number of SCs or thermal colloids at regularly spaced distances and averages are taken in steady state, i. e. after reasonably long time after initialization.

187 show faster relaxation compared to the BD system. For larger structures (small q), the SCs
 188 in tissue relax significantly faster compared to the thermal colloids due to their superdiffusive
 189 motion. The enhanced relaxation with increased structure size holds for all q as can be seen
 190 from the half life relaxation time (see App. E Fig. 15).

191 6 Stem cell repulsion in three dimensions

192 Many biological tissues are not restricted to two dimensions, but extend to the third dimension,
 193 which is especially the case in cancer, where cells grow out of plane and form spheroidal
 194 tumors. We show that the effect of repulsion by progeny is not limited to two dimensions and
 195 can also be found in tissue simulations in three dimensions (see Fig. 5). Qualitatively, the
 196 pair correlation function shows the same repulsion of SC at a distance corresponding to the
 197 volume of their progenitors. Note that here the geometric normalization of the pair correlation

function is the volume of a sphere instead of the area of a circle around the stem cell.

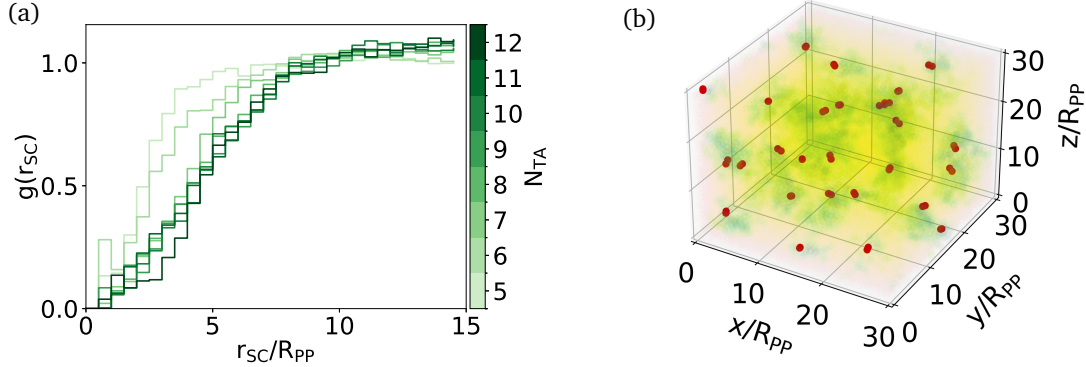

Figure 5: **Stem Cell repulsion qualitatively remains in three dimensions.** (a) Pair correlation function for stem cells in three dimensions shows reduced probability to find SCs at short distances, and plateau at longer distances. (b) Snapshot for a three dimensional tissue with $N_{TA} = 10$ after 50 generations. All simulations are performed with 27 SCs in a cubic box with box length $30 R_{PP}$.

198

199 7 Independence of homeostatic pressure controlled divisions

200 Stem cells interacting effectively via their (growing) progeny is a robust effect in tissues with
 201 mechanical cell-cell interactions. We show this by replacing the division after reaching a size
 202 threshold, which introduces a feedback on the homeostatic pressure, by stochastic divisions
 203 with fixed rate k_d . This rate is set to the measured division rate in the size threshold division
 204 model for an exemplary tissue with $N_{TA} = 6$. Details on the implementation can be found in
 205 Appendix F.

206 The distribution of TA cells around the SC remains almost unchanged (see Fig. 6a), thus,
 207 also the SC pair correlation function of both models remains the same (see Fig. 6b). The SC
 208 dynamics, measured by the MSD, remains unchanged as well (see App. F Fig. 17). Thus, the
 209 mechanical cell-cell interactions in the model and outflux of cells from the SC are generating
 210 an effective SC repulsion, but not the feedback of growth and division on pressure in the tissue.

Figure 6: **Relevance of homeostatic pressure growth control.** (a) Snapshot for deterministic TA cell differentiation ($N_{TA} = 6$) in the model with stochastic division mechanism. (b) Pair correlation function for simulation model with division after reaching a size threshold (red) and stochastic divisions (blue).

211 8 Discussion and conclusion

212 In this work, we have studied the dynamics of stem cells in self-renewing tissues driven by
213 mechanical interactions. Due to the constant outward flow of progeny generated by stem
214 cells, we find that SCs effectively repel each other and spontaneously organize into dispersed
215 structures with a corona of their progeny. This provides an updated and more biophysical
216 view of the classical concept of proliferating units in tissues, in which size and shape of self-
217 renewing domains are flexible, but still organized by stem cells which are robustly present
218 within each unit [19].

219 Interestingly, we find that the interaction between stem cells can be largely described in
220 a simplified fashion with help of an effective equilibrium approach. The assumption purely
221 repulsive interaction and determination of the interaction length from the spatial requirements
222 for the progeny produced by each stem cell division allows us to characterize SCs like very soft
223 colloids, which interact via this effective repulsive interaction – much larger than the cell size.
224 Further, we have shown that this simplified model reproduces the structural results of the
225 two-particle growth model in confluent tissues. The pair correlation function of the thermal
226 colloids is remarkably similar to that of actively growing cells. The dynamics however are
227 different. We show evidence of an active and persistent self-propulsion force acting on SCs
228 due to the surrounding growing cells. We systematically characterize these, in particular in
229 terms of the statistics and active nature of their persistent random walks. As a result of this
230 proliferation-driven movements, the confluent tissue shows faster relaxation characteristics
231 on long time and length scales. The only detectable difference between the actively growing
232 tissue and the thermal colloid system was found in the dynamic structure factor. It shows a
233 speedup of large structure relaxations in the tissue model due to its active nature, and thus
234 confirms that the active system can be mapped surprisingly well to an thermal equilibrium
235 system.

236 The derivation of an effective interaction using nearest neighbor distribution functions and
237 mapping it on particle systems may lack sensitivity to certain characteristics of the interaction,
238 especially with increasing density [20, 21]. However, they are still able to capture the main
239 influences of the interaction. Further, replacing the passive Brownian particle system by an
240 active one, is very likely to fail as the continuously decrease of activity enhanced motion cannot
241 be derived from first principles of infinitely diluted systems [22].

242 Small populations of SCs dispersed within the tissue were also shown to be particularly
243 susceptible to tumor formation in mouse epidermis [23] as well as to have large contribution
244 upon wound healing [24], which could also be investigated via our simulation framework.
245 Furthermore, spermatogenic stem cells are also found to be well separated in the planar basal
246 layer in mouse testis, and show a striking similarity to the stem cell arrangement found in our
247 simulations [25]. Other models of the formation of epithelial protrusions and location of stem
248 cells on the tips of these have been studied previously using a particle-based model [26]. By
249 adding substrate deformability and cell type dependent adhesion forces, the model displayed
250 a stable stratified epithelium with stem cells located at protrusions. It will be interesting to
251 combine these models.

252 The homogeneous distribution of stem cells arising from our purely mechanical feedback
253 model may complement previous studies [3, 4], in which this was achieved with help of a
254 reversible differentiation scheme or biochemical feedback mechanisms based on diffusible sig-
255 nals. However, in reality, a combination of several of these mechanisms will likely be relevant,
256 also depending on the tissue type. In particular, stochastic cell fate models may be of great

257 interest in the future and could facilitate the description of the plasticity of cells during tissue
258 repair [27, 28]. Also, there exists evidence that more than one SC type maintains some tis-
259 sues [29, 30] or that cell fates are reversible processes [3, 31], which could be readily integrated
260 in our simulation framework. In the presence of local niches, it has also been shown that the
261 ratio of proliferation to random cell movements determines the effective number of stem cells
262 via a mechanism of stochastic competition for space, although this has not been modeled via
263 explicit mechanical simulations [32, 33]. Until now, the vanishing apoptosis rate of SCs and
264 restriction to only asymmetric SC divisions in our model are limiting factors. Allowing for
265 SC apoptosis, or other processes which reduce the SC number, requires symmetric duplica-
266 tion to balance the SC loss to retain their unique identity in the lineage architecture [34].
267 Furthermore, it would be interesting to see if a purely mechanical model is able to capture
268 the alternation from a quiescent long-lived SC to produce rapidly dividing short-lived progeny
269 during wound repair [35–37].

270 In this work, we find surprising motility of cells emerging from the interaction of cells
271 with each other. While epithelial cells are generally not motile, motility occurs after epithelial-
272 mesenchymal transformation (EMT) [38], or in some cell lines, in particular MDCK. Active cell
273 migration has been the subject of related work [39–41] and recent findings show that active
274 cell migration does play a role in tissue renewal [42], thus, displaying a promising extension
275 of our work in future studies.

276 Many aspects of growing tissues have not been addressed in this work. In particular we did
277 not address the role of boundaries and interfaces. Especially in competition setups [8–11, 43]
278 the interface plays a dominant role over the resulting structure. Similarly, three dimensional
279 cell culture is often performed in tissue spheroids, where growth at the surface stabilizes the
280 internal tissue [7, 18, 44, 45] and the dynamics can drive phase separation [46, 47]. A second
281 aspect not addressed here is the rheology or flow response of the tissue. “Analogies between
282 growing dense active matter and soft driven glasses” [48] have been discussed a lot in the
283 literature. In particular, if tissues are generically liquid-like due to cell turnover [6, 49], and
284 if cell density [50], cell shape [51], or cell-cell adhesion [41] drive a glass like transition on
285 timescales short compared to cell turnover. For a review of further unique properties of self
286 replicating systems like injection of degrees of freedom or giant fluctuations see [52].

287 Finally, our results might contribute to a better understanding of the growth and dynamics
288 of cancer. In the cancer stem cell (CSC) hypothesis, it is assumed that malignant tissue follows
289 the same underlying stem cell dynamics. Therapies, which target fast growing tissue, fail,
290 since the stem cells evade. A better understanding of the dynamics of CSCs could improve
291 their detection and the design of therapies. Our results would suggest, that CSCs are isolated
292 and well spread throughout the tumor. To further tackle these questions, it will be necessary
293 to combine our model, with models of cellular competition [5, 7–9, 11], and taking the cell
294 cycle explicitly into account might be essential [53, 54]

- 306 • *S2 Video Isolated stem cell.* Animation of isolated SC performing random walk with
 307 long persistent segments (see Fig. 2a and sec. D).
- 308 • *S3 Video Stem cell interaction.* Animation of two SCs interacting with each other via
 309 their progeny (see Fig. 2b).
- 310 • *S4 Video Interaction in Tissue and BD simulations.* Animation of confluent tissue and
 311 thermal colloids (see Fig. 3a and Fig. 3b).

312 B Simulation model

313 The described SC model is implemented in the two-particle growth (2PG) model of Refs. [7,17]
 314 and has been adapted in Refs. [9–11].

315 Each cell is described by two particles, which repel each other via an active growth force

$$F_{ij}^{(G)} = \frac{G}{(r_{ij} - r_0)^2} \hat{r}_{ij} \quad (2)$$

316 with unit vector \hat{r}_{ij} , distance r_{ij} between the two particles, a constant r_0 , and growth strength
 317 G . For non-growing cells, like TD cells, the growth strength is set to zero, $G_{TD} = 0$, and for
 318 the sake of simplicity SC and TA cells have the same growth force, $G_{SC} = G_{TA}$.

319 To prevent overlap of cells, particles of different cells interact via a soft repulsive volume-
 320 exclusion force

$$\mathbf{F}_{ik}^{(V)} = f_0 \left(\frac{R_{PP}^5}{r_{ik}^5} - 1 \right) \hat{r}_{ij}, \text{ for } r_{ik} < R_{PP} \quad (3)$$

321 with exclusion strength f_0 and interaction length R_{PP} , which sets the length scale of our sim-
 322 ulations. Further, cells in contact interact via an attractive adhesion force of the form

$$\mathbf{F}_{ik}^{(V)} = -f_1 \hat{r}_{ik}, \text{ for } r_{ik} < R_{PP} \quad (4)$$

323 with adhesion strength f_1 .

324 We employ a dissipative particle dynamics-type thermostat [55], with an effective temper-
 325 ature T , to account for energy dissipation

$$F_{ij}^{(D)} = \gamma \cdot \left(1 - \frac{dr}{rt} \right)^2 \cdot (\mathbf{v}_{ij} \cdot \mathbf{r}_{ij}) \quad (5)$$

326 and random fluctuations

$$F_{ij}^{(R)} = \sigma \xi \cdot \hat{r}_{ij} \quad (6)$$

327 where γ and σ are related to fulfill the fluctuation-dissipation theorem [56]. Also, background
 328 dissipation is taken into account as

$$\mathbf{F}_i^B = -\gamma_b \mathbf{v}_i. \quad (7)$$

Table 1: Simulation parameters of the standard tissue.

Parameter	Symbol	Value
Time step	Δt	0.001
Pair potential interaction range	R_{PP}	1
Cell expansion constant	r_0	1
Division distance threshold	R_{ct}	0.8
New cell particle initial distance	R_d	10^{-5}
Growth-force strength	G	50
Mass	m	1
Intra-cell dissipation coefficient	γ_c	100
Inter-cell dissipation coefficient	γ_t	50
Background dissipation coefficient	γ_c	0.1
Apoptosis rate	k_a	0.01
Noise intensity	$k_B T$	0.1
Repulsive cell-cell potential coefficient	f_0	2.39566
Attractive cell-cell potential coefficient	f_1	3.0

329 A self-consistent velocity-Verlet algorithm [57] is implemented to integrate the equations
 330 of motion, and all simulations were performed with periodic boundary conditions.

331 Cell division is performed, when the two particles of one cell are separated by a critical
 332 threshold R_{ct} . A new particle is randomly placed near each original particle in a distance R_d ,
 333 and the two new particle pairs form the two daughter cells. Differentiation is implemented at
 334 the time of division as described above, and the number of divisions of TA cells is tracked by
 335 an internal variable. No mechanism is implemented to prevent (non-growing) TD cells from
 336 separating. However, we observe only a marginal number of TD cell divisions in simulations
 337 of isolated SCs and SC pairs in free space, and none for confluent tissues. The TD cell size in
 338 confluent tissues is always far below the division threshold (see Fig.16), but slightly increases
 339 with distance, which is found more pronounced for TD cells generated by SCs in free space
 340 (data not shown).

341 TA and TD cells are stochastically removed from the simulation with a finite apoptosis rate
 342 k_a . For simplicity, the same rate is chosen for different cell types. Time is measured in terms
 343 of the inverse apoptosis rate, and referred to as "generation".

344 The standard parameter set for our simulations are given in Tab. 1. However, not all of
 345 these simulation parameters, have a direct conversion to physical units. As discussed in [17]
 346 one has to chose well defined measurable quantities, such as apoptosis rate and range of the
 347 pair potential as rescaling units for inverse time and particle diameter, to allow for conversion
 348 to physical units and comparison with experiments.

349 As the number of stem cells in our simulation is fixed by only allowing for asymmetric
 350 divisions and no apoptosis, we initialize all simulations with the required number of stem
 351 cells, placed at regular distances within the unit box with periodic boundary conditions.

352 C Division rate of isolated SC

353 Assuming equal division rates k_d for all types of proliferating cells, we can derive an average
354 cell number from number balance for each cell type

$$\begin{aligned} n_{SC} &= \langle n_{SC} \rangle = \text{const.} \\ \langle n_i \rangle &= 2^{i-1} \left(\frac{k_d}{k_d + k_a} \right)^i n_{SC} \\ \langle n_{TD} \rangle &= \left(\frac{2k_d}{k_d + k_a} \right)^{N_{TA}} \frac{k_d}{k_a} n_{SC}, \end{aligned} \quad (8)$$

355 where i denotes the TA cell cycle. k_d is obtained from fitting these equations to the cell numbers
356 obtained from simulations of isolated SCs. With increasing N_{TA} , the division rate decreases (see
357 Fig. 7).

Figure 7: Division rate k_d as function of N_{TA} for proliferating cells in isolated SC simulations.

358 D Stem cell motion

359 Here, we give some additional insight in the SC motion of isolated SCs and SCs in tissues,
360 which are also discussed in the main text.

361 An exemplary single stem cell snapshot for $N_{TA} = 4$ is shown, where the SC trajectory over
362 ten generations illustrates the motion of the SC, and accompanied The full trajectory of the SC
363 and center of mass of the respective single stem cell simulation along both directions of the
364 simulation plane (see Fig. 8).

365 D.1 Mean squared displacement of isolated stem cells and stem cells in tissues

366 For active Brownian particles (ABPs) in two-dimensions the mean squared displacement MSD
367 is given as [58, 59]

$$MSD = 4 D_t \Delta t + \frac{v_0^2 \tau_R^2}{2} \left[\frac{2\Delta t}{\tau_R} + e^{-2\Delta t/\tau_R} - 1 \right], \quad (9)$$

368 with translational diffusion coefficient D_t , characteristic time scale for rotational diffusion τ_R ,
369 and propulsion velocity v_0 . In the short-time limit $d t \ll \tau_R$ the effective diffusion is given by
370 $MSD_{d t \ll \tau_R} \approx 4 D_t d t$. For long-time diffusion the effective diffusion is enhanced and the MSD

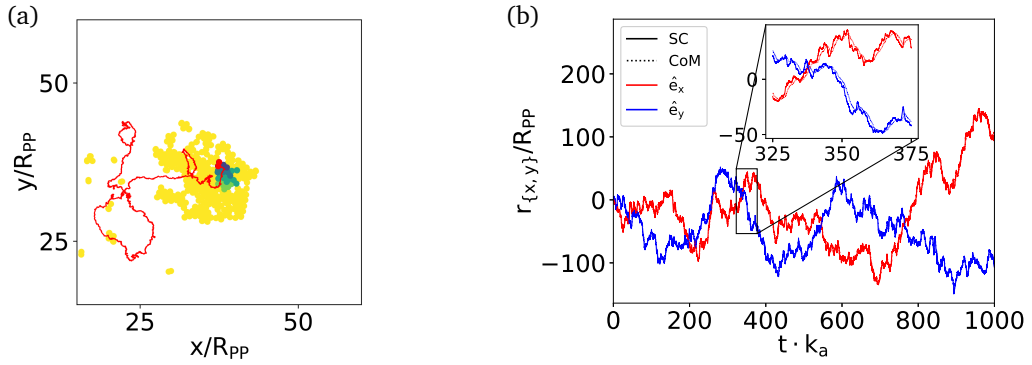

Figure 8: (a) Snapshot of cell population generated by a single SC with trajectory of SC over the ten cell generations (red line). (b) Trajectory of isolated SC (solid line) and center of mass (CoM) of cell population (dotted line) along \hat{e}_x (red) and \hat{e}_y (blue). Inset shows time close-up to highlight how the center of mass follows the stem cell motion. Both, SC and CoM trajectory perform a random walk with surprisingly long persistent segments, a reminiscent of Run'n'Tumble-like motion. Simulation with $N_{TA} = 4$ is shown.

371 found to be $MSD \approx (4D_t + v_0^2 \tau_R) dt$, again linear in time. Between these two regimes, ballistic
 372 motion is observed, and non-linear terms enters the MSD, $MSD \approx 4D_t dt + v_0^2 dt^2$.

373 In the tissue simulations, the stem cells are not ABPs, but move actively due to propulsion
 374 by progeny. However, we can quantify the dynamics of the stem cell motion in terms of D_t , τ_R ,
 375 and v_0 to gain a deeper understanding. Also different models of self-propelling particles, like
 376 ABPs and Run'n'Tumble particles have been shown to be equivalent on larger scales [60, 61],
 377 so that we can describe them using the same theory, without making strong assumptions on
 378 the underlying propulsion mechanisms.

379 From the MSDs for simulations of SCs with varying number of TA cell cycles N_{TA} (see
 380 Fig. 9), one can see that the displacement does vary little with a change of N_{TA} . In particular the
 381 short-time diffusion decreases with N_{TA} , which could be due to blocking of cell motion at higher
 382 density. This resembles the decrease of the translational diffusion coefficient D_t with N_{TA} . The
 383 long-time diffusion first increases with N_{TA} , but then starts to decrease again. Possibly, in
 384 increasing number of TA cells around the stem cell initially increases the propulsion force on
 385 the stem cell, but saturates at higher number of progeny, which form a more dense halo around
 386 the stem cell for more TA cell cycles. The non-monotonic fit parameter for the self propulsion
 387 velocity, with maximum at $N_{TA} = 6$, and increasing characteristic rotational diffusion time τ_R
 388 show, that the decrease in propulsion velocity does cause the effective decrease of the long-
 389 time diffusion with $N_{TA} > 6$. The characteristic rotational diffusion time τ_R is found to be in
 390 the range from half to more than one apoptosis time, which corresponds to a loss of orientation
 391 after times larger than one cell generation.

392 In tissues, we still can apply the MSD theory to fit to the SC displacement (see Fig. 10). With
 393 increasing cell density, controlled by an increase in SC numbers, we find that the translational
 394 diffusion coefficient D_t and propulsion velocity v_0 decrease, and the SC motion freezes out.
 395 The rotational diffusion time is not as strongly effected by the cell density, and approximately
 396 half the value compared to the case of an isolated SC, since it is mainly affected by the apoptosis
 397 rate.

398 D.2 Displacement distribution

399 To quantify the persistent motion further, we calculate the displacement distribution function
 400 and find heavy tails. The heaviness of the tails increases, when the SC is located further away

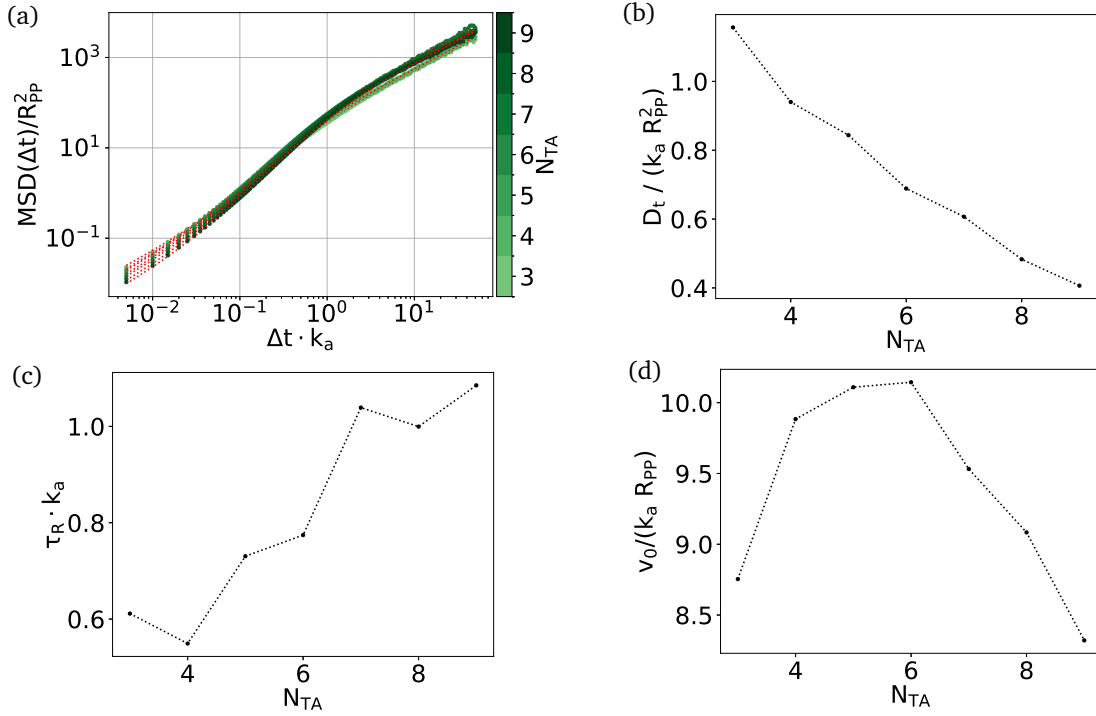

Figure 9: (a) Mean squared displacement for isolated SCs with different N_{TA} (color coded) and fit of ABP model (red dotted lines). (b) Translational diffusion coefficient D_t , (c) characteristic rotational diffusion time τ_R , and (d) propulsion velocity v_0 obtained from fit function in (a).

401 from the center of mass in the boundary region of the cell population (see Fig. 11).

402 D.3 Overdamped dynamics

403 The applied self-consistent velocity Verlet integration of the Langevin equations allows for large
 404 integration time steps and therefore provides significant faster computations [62]. Effectively,
 405 using a finite mass and velocity Verlet integration corresponds to using a higher order integra-
 406 tor with a physically interpretable control parameter, the mass of cells. However, care has to be
 407 taken to reproduce overdamped dynamics, which is achieved by setting mass and friction coef-
 408 ficients such that the viscous relaxation time is much shorter than all other relevant timescales,
 409 i. e. that viscous drag dominates over inertia even at short timescales. Because inertial effects
 410 scale with the mass of the particles, correct reproduction of overdamped dynamics can be ver-
 411 ified by showing independence of the results on mass. As an example, we measured the self
 412 propulsion of a single stem cell over two orders of magnitude in mass (see Fig. 12). The results
 413 are virtually indistinguishable, confirming correct reproduction of overdamped dynamics .

Figure 10: (a) Mean squared displacement for SCs in tissue with different cell density (color coded) controlled by the stem cell number, with $N_{TA} = 6$. (b) Translational diffusion coefficient D_t , (c) characteristic rotational diffusion time τ_R , and (d) propulsion velocity v_0 obtained from fit function in (a).

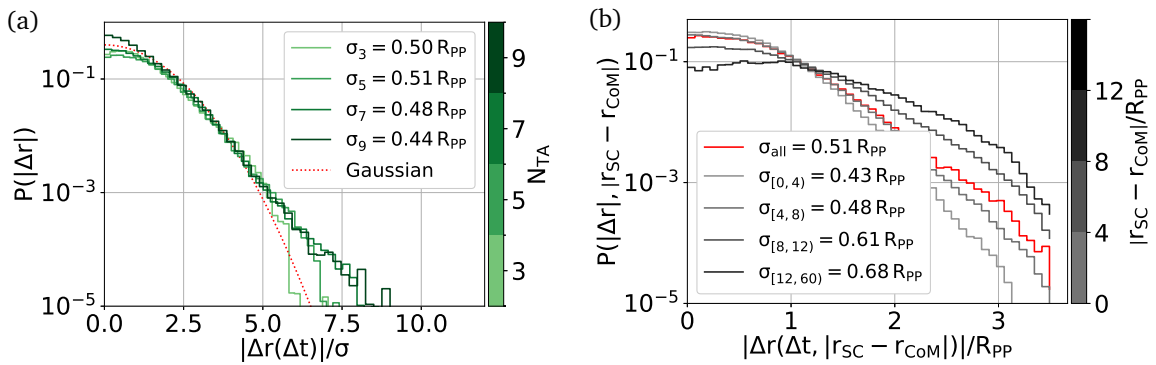

Figure 11: (a) Displacement distribution for an isolated stem cell with different N_{TA} (green color gradient) over normalized displacement. Red dotted line displays normal displacement (Gaussian). Heavy tails emerge from long consistent segments of random walk. (b) Displacement distribution as in (a) for isolated SC with $N_{TA} = 5$, where color gradient (grey) encodes SC-to-CoM distance. With increasing distance heaviness of tails increases. All displacements are calculated for a time step of $\Delta t k_a = 0.2$ generations, combining data of multiple long simulation runs.

Figure 12: (a) Mean squared displacement for isolated SCs for simulations with different cell masses m (purple color gradient). All simulations are performed with $N_{TA} = 6$.

414 E Additional results for simulations of stem cells in tissues

415 E.1 Cell densities in confluent tissues

416 In confluent tissue simulations, we chose the SC number and N_{TA} such that an uninterrupted
 417 tissue evolves. Still, the TD cell density around SCs remains very similar to the case of iso-
 418 lated SCs. The TD cells are located closer to the SCs and form a more dense conglomerate.
 419 Exemplary cell densities for $N_{TA} = 6$ are shown in Fig. 13a.

420 The total cell density of tissues with different N_{TA} is controlled by the number of SCs in
 the simulation, and chosen such that they are all very similar (see Fig. 13b).

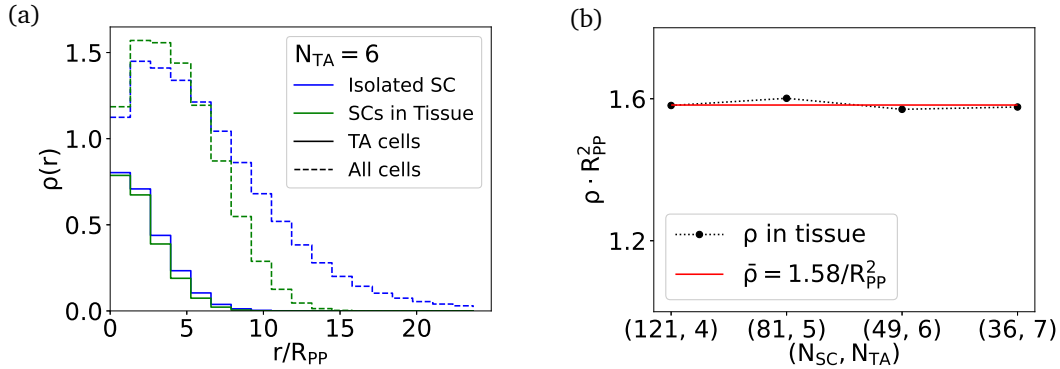

Figure 13: (a) Cell density of TA (solid line) and all (dashed line) cells around the SC for simulations of an isolated SC (blue) and SCs in tissue (green). In tissue, distance is measured to the closest SC. (b) Average cell density of tissue simulations as function of N_{SC} , the fixed number of SC, N_{TA} obtained from average cell number over box area.

421

422 E.2 Cluster analysis

423 To quantify the clustering of SCs in tissues, we calculate the cluster size distribution function
 424 is given by

$$\mathcal{N}(n) = \frac{1}{N_{SC}} n p(n) \quad (10)$$

425 and represents the fraction of SCs belonging to a cluster of size n , where $p(n)$ is the number
 426 of clusters of size n . The distribution is normalized such that $\sum_{i=1}^{N_{SC}} = 1$. The average cluster
 427 size is given as

$$\langle n \rangle = \frac{\sum_n n p(n)}{\sum_n p(n)} \quad (11)$$

428 Cells in a distance less than the characteristic TA cell distance estimated from cell numbers
 429 belong to the same cluster. Results are shown in Fig. 14.

430 E.3 Effective diffusion coefficient and relaxation

431 The timescale for the thermal colloid simulation in the main text was adjusted by matching
 432 the short term diffusion obtained from the MSD of SCs in the tissue simulations. Here, we
 433 calculate the effective diffusion coefficient D_{eff} from the intermediate structure factor. For
 434 the relaxation of structures it holds

$$\frac{S(q, \Delta t)}{S(q, 0)} = e^{-D_{eff}(q) \Delta t q^2}, \quad (12)$$

Figure 14: (a) Same as Fig. 3d (b) Average cluster size as function of N_{TA} remains clearly below two SC.

435 which yields

$$D_{eff}(q) = \log \left\{ \frac{S(q, \Delta t)}{S(q, 0)} \right\} / (q^2 \Delta t). \quad (13)$$

436 Now, we can measure the effective diffusion for short time lags (here: $0.02k_d$) and see that
 437 both models show the same short term diffusivity, as should be (see Fig. 15a).

438 The relaxation of structures is obtained from the half-life relaxation time of $S(q, t)/S(q, 0)$.
 439 We find that this time decreases with q , which means that smaller structures relax faster. Fur-
 440 ther, in the tissue model structures relax faster than in the thermal colloid system and the
 relaxation speeds up with structure size (see Fig. 15b).

Figure 15: (a) Effective diffusion coefficient D_{eff} measured from structure factor relaxation for $\Delta t = 0.2k_d$. (b) Relaxation half life time as function of q .

441

442 F Stochastic division rate model

443 The observed separation of stem cell in tissues is a generic effect arising from short range
 444 mechanical interactions between pairs of cells. To highlight this, we replace the size-threshold
 445 division (STD) mechanism by a stochastic division with fixed rate \tilde{k}_d (SDR). This turns off the
 446 homeostatic pressure control on divisions. We determine the simulation parameter \tilde{k}_d for the
 447 SDR model from measurements of k_d in the STD model. Only the case of tissues with $N_{TA} = 5$
 448 is examined.

449 To implement, that cells do not divide at too small size and cause computational flaws, we
 450 replace the growth force by a damped harmonic oscillator

$$\mathbf{F}_{i,j}^{Gharm.} = -k\mathbf{x} - \gamma_k \dot{\mathbf{x}}, \quad (14)$$

451 where $k = 100$ is the spring constant, and $\gamma_k = 20$ the damping coefficient, chosen in a way
 452 to realize critical damping with relaxation time faster than the average division time. The
 453 deflection $\mathbf{x} = (|\mathbf{r}_i - \mathbf{r}_j| - R_{rest}) \hat{\mathbf{e}}_{ij}$ is given by the difference between cell size and rest length
 454 R_{rest} . We set the rest length of proliferating cells, i.e. SC and TA cells, to $R_{rest}^{SC,TA} = R_{ct} = 0.8R_{pp}$
 455 and for TD cells to $R_{rest}^{TD} = 0.1R_{pp}$.

456 Despite the fact that we tune the oscillator such that cells grow quickly to a adequate
 457 size, some cells divide at very small size and cause computational chaos. To prevent this,
 458 we introduce a minimum division size, much smaller than the division size threshold used
 459 previously. With $R_{min} = 0.15R_{pp}$ we can ensure stable behavior of the computational model
 460 after division.

Figure 16: (a) Complementary cumulative distribution function (cCDF) for apoptosis (blue), division events including prevented divisions due to small size (orange), and performed divisions (green). Black dotted line highlights longest time for a prevented division event. Black dashed lines display median of each cCDF. (b) Cellsize distribution for proliferating (SC and TA cells, solid line) and TD cells (dotted lines) in the stochastic division model (blue) and for size threshold divisions (red).

461 Figure 16a displays the complementary cumulative distribution function (cCDF) of apopto-
 462 sis, division, and non-permitted division events, i.e. division events at too small cell size. Only
 463 a small fraction of events at very short times is permitted and thus, we sufficiently removed
 464 the size-threshold division mechanism. Further, the cell size distribution (see Fig. 16b) shows,
 465 that TD cells in both models match each other well, and for growing cells, we find that the
 466 hard division size threshold changes to a blurred tail. The stochastic division model has equal
 467 number of TA cells, both in total and for each generation, and did produce only slightly more
 468 TD cells. However, cell numbers fluctuate more, which can be to the detriment of stable tissue
 469 homeostasis.

470 When comparing both models, we find that SCs are still surrounded by their TA cell cloud.
 471 In the stochastic division model the TA cell arrangement around the stem cells looks more
 472 fringed compared to the deterministic model but no large differences can be found in the
 473 measured TA cell distribution (see Fig. 17a, 17b). Still, for both models, the pair correlation
 474 function agree very well (see Fig. 17c) and the activity of SC in the tissue remains almost
 475 unchanged (see Fig. 17d).

476 We conclude that the results discussed in the main text are not a consequence of homeo-
 477 static pressure growth control, but result from the constant cell outflux generated by the SC.
 478 Yet, the pressure feedback on divisions is beneficial to balance cell numbers in the tissue to
 479 ensure homeostasis.

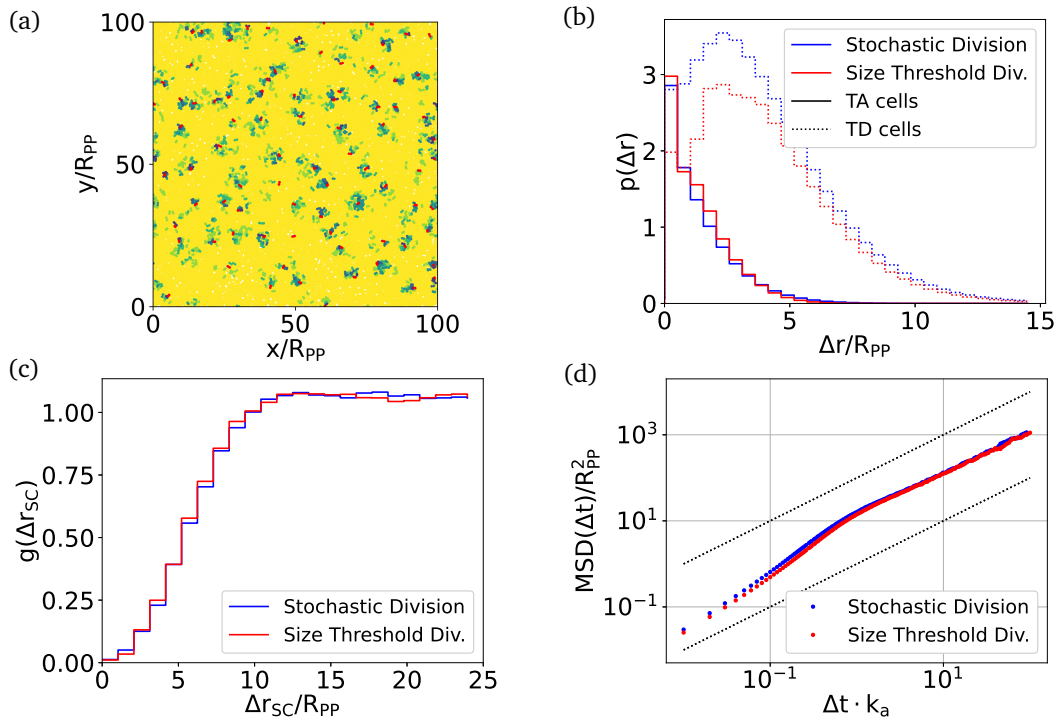

Figure 17: (a) Snapshot for stochastic division model, (b) TA and TD cell distribution around nearest neighbor SC in tissue, (c) pair correlation function, and (d) Mean squared displacement for the respective models. For comparison, stochastic division model is shown by blue lines together with results for model with size threshold division for $N_{TA} = 5$.
