### Abstract

Molecular sorting in biological membranes is essential for proper cellular function. It also plays a crucial role in the budding of enveloped viruses from host cells. We recently proposed that this process is driven by phase separation, where the formation and growth of sorting domains depend primarily on short-range intermolecular interactions. In addition to these, Casimir-like forces—arising from entropic effects in fluctuating membranes and acting on longer ranges—may also play a significant role in the molecular distillation process. Here, using a combination of theoretical analysis and numerical simulations, we explore how these forces contribute to sorting, particularly in the biologically relevant regime where short-range intermolecular interactions are weak. Our results show that Casimir-like forces enhance molecular distillation by reducing the critical radius for the formation of new sorting domains and facilitating the capture of molecules within these domains. We identify the relative rigidity of the membrane and supermolecular domains as a key parameter controlling molecular sorting efficiency, offering new insights into the physical principles underlying molecular sorting in biological systems.

## 12 **1 Introduction**

13 Molecular sorting is a vital process in eukaryotic cells, where proteins and other biomolecules  
14 are sorted and encapsulated into lipid vesicles for targeted transport to specific subcellular  
15 locations. This distillation process occurs on lipid membranes, such as the plasma mem-  
16 brane [1], endosomes, the Golgi apparatus [2], and the endoplasmic reticulum [3], where  
17 biomolecules can bind and diffuse laterally. Due to a variety of direct and indirect interactions,  
18 these molecules aggregate into domains with distinct chemical compositions. These domains  
19 can induce membrane bending and fission [4–7], ultimately forming separated submicron lipid  
20 vesicles that are transported to their designated subcellular sites by molecular motors. In this  
21 way, lipid membranes act as natural molecular distillers, promoting intracellular order and  
22 compartmentalization and counteracting the homogenizing effects of diffusion. Disruption of  
23 molecular sorting in living cells is implicated in severe pathologies, including cancer [8, 9].  
24 On the other end of the spectrum, analogous molecular sorting processes are exploited by en-  
25 veloped viruses, such as HIV, SARS-CoV, and influenza, for their assembly and budding from  
26 host cells [10–13], further underscoring the practical relevance of understanding the physical  
27 mechanisms of molecular sorting.

28 We have recently proposed a simple model of molecular sorting as a phase-separation pro-  
29 cess. In this context, the efficiency of sorting is found to be optimal at intermediate values  
30 of intermolecular attraction forces [14–16]. This theoretical prediction is consistent with ex-  
31 periments on endocytic sorting in living cells under near-physiological conditions [14], and  
32 with measurements performed on photoactivated systems, where the strength of intermolec-  
33 ular attraction can be directly controlled [17]. The interpretation of molecular sorting as a  
34 phase-separation process is also coherent with the observation that sorting domains in living  
35 cells exhibit a critical size: only supercritical (“productive”) domains evolve into lipid vesicles  
36 that are extracted from the membrane, while subcritical (“unproductive”) domains are rapidly  
37 dissolved [15, 18].

38 Phase separation is emerging as one of the main ordering processes in living cells [19–  
39 21], and various mechanisms have been proposed as its drivers. Among them, weakly po-  
40 lar electrostatic interactions between disordered regions of proteins [22], active processes,  
41 as in diffusion-limited phase separation, mass-conserved reaction-diffusion systems and ac-  
42 tive emulsions [23–29], and segregating kinetic effects [30]. On the other hand, it has long  
43 been established that protein inclusions in lipid membranes are subject to Casimir-like interac-  
44 tions [31, 32, 49], a significant class of entropic interactions. However, their role in molecular  
45 sorting remains unexplored. These interactions arise from the increased rigidity of the mem-  
46 brane in the presence of embedded protein inclusions, which restricts membrane fluctuations  
47 and generates entropic attractive forces. It is known that proteins and lipids involved in the for-  
48 mation of sorting domains increase local membrane rigidity by a factor of 10 to 30 compared to  
49 the surrounding membrane [33–35]. Here, we investigate the role of these Casimir-like inter-

50 actions in molecular sorting and find that they can significantly enhance the molecular sorting  
51 process, especially within the biologically relevant regime of weak short-range interactions.

## 52 2 Phenomenological Theory

53 Building on our previous work, we investigate the role of the lipid membrane as a distiller of  
54 molecular species [14–16]. In this scenario, molecules are randomly inserted into the mem-  
55 brane, diffuse laterally, and aggregate into sorting domains due to short-range attractive forces.  
56 The sorting domains grow by adsorbing molecules from the surrounding “gas” of freely dif-  
57 fusing molecules. Domains of size  $R$  larger than a critical value  $R_c$  grow irreversibly through  
58 the absorption of single molecules diffusing towards them [15, 36, 37]. The growth rate is  
59 determined by the net flux  $\Phi$  of molecules towards a domain, which in turn is proportional to  
60 the molecular density difference  $\Delta n = n_L - n_R$  between distant regions and regions adjacent  
61 to the domain boundaries [14]. Domains that reach a characteristic size  $R_E$  are ultimately  
62 removed from the membrane through the formation of small, separate lipid vesicles [14].

63 Of particular interest is the stationary out-of-equilibrium regime, where molecular inser-  
64 tion and extraction processes are balanced. This balance can be described by the equation

$$\phi = N_d \Phi, \quad (1)$$

65 where  $\phi$  is the flux density of molecules being inserted into the membrane,  $N_d$  is the density  
66 of supercritical domains, and  $\Phi$  is the average flux of the molecules into a domain. In this  
67 regime, unlike in the classical Lifshitz-Slezov scenario [36, 37], the flux-driving jump  $\Delta n$  in  
68 molecular density is kept finite by the continuous influx  $\phi$  of molecules into the membrane.

69 We have shown in Ref. [14] that an optimal sorting regime is achieved for an intermedi-  
70 ate strength of short-range attractive forces. When the tendency to aggregate is too strong,  
71 a proliferation of slowly growing sorting domains occurs, leading to molecular crowding and  
72 decreased sorting efficiency [14, 16]. In the optimal sorting regime, there exists a specific  
73 density  $N_d$  of sorting domains, resulting in minimal average molecular density [14]. For ab-  
74 sorbing domains, the average residence time  $T$  of a molecule of linear size  $a$  in the membrane  
75 system is the sum of the average time  $T_f$  required for the molecule to reach a sorting domain  
76 by free diffusion and be absorbed, and the average time  $T_d$  spent inside the domain until the  
77 extraction event. The two contributions can be estimated as [14]

$$T_f \sim \frac{1}{DN_d}, \quad T_d \sim \frac{(R_E/a)^2}{\phi} N_d,$$

78 where  $D$  is the molecular diffusion coefficient. The sum  $T = T_f + T_d$  has a minimum for

$$N_{d,\text{opt}} \sim \frac{a}{R_E} \sqrt{\frac{\phi}{D}}. \quad (2)$$

79 The actual density  $N_d$  is a function of the microscopic properties of the system that control the  
80 nucleation and growth of domains in the stationary state, but irrespective of the combination  
81 of these microscopic quantities, the optimal residence time of molecules on the membrane has  
82 the value determined by Eq. (2).

83 To account for the role of membrane fluctuations in the molecular sorting process described  
84 above, we recall that the equilibrium thermal fluctuations of an elastic membrane are described  
85 by the Helfrich Hamiltonian,

$$\mathcal{H} = \int dS \left[ \frac{\kappa}{2} \left( \frac{1}{R_1} + \frac{1}{R_2} \right)^2 + \frac{\bar{\kappa}}{R_1 R_2} \right], \quad (3)$$

86 where the integral runs over the membrane surface,  $dS$  is the area element,  $R_1, R_2$  are local  
 87 principal curvature radii, and  $\kappa, \bar{\kappa}$  are the bending rigidities associated with the mean and  
 88 Gaussian curvatures, respectively [38–40]. As argued in Refs. [41–43], for biological mem-  
 89 branes,  $\bar{\kappa}$  is close to  $-\kappa$ . While our theory remains valid for any relation between  $\kappa$  and  $\bar{\kappa}$ ,  
 90 for simplicity we will assume that  $\bar{\kappa} = -\kappa$  in the numerical computations presented in the  
 91 following section. In the presence of protein inclusions, the rigidity of the membrane becomes  
 92 spatially non-uniform. Here, we assume that  $\kappa(\mathbf{r}) = \kappa_0$  for the bulk membrane, and  $\kappa(\mathbf{r}) = \kappa_1$   
 93 in the regions occupied by the molecules. A surface-tension contribution to the energy could  
 94 also be included, but it is assumed to be negligible and will not be considered here.

95 We further assume that the diffusive dynamics of protein inclusions is slower than the  
 96 fluctuational dynamics of the underlying membrane, i.e.,  $\tau_{\text{diff}} \gg \tau_{\text{rel}}$ , with  $\tau_{\text{diff}}$  the charac-  
 97 teristic diffusion time and  $\tau_{\text{rel}}$  the characteristic membrane relaxation time. This is motivated  
 98 by the following estimates. The characteristic time for lateral diffusion can be estimated as  
 99  $\tau_{\text{diff}} \sim \lambda^2/D$ , where  $\lambda$  is the characteristic scale of the problem. Assuming that the viscosity  
 100  $\eta$  of the cytosol is the primary source of dissipation, the characteristic relaxation time of the  
 101 membrane dynamics is  $\tau_{\text{rel}} \sim \eta\lambda^3/\kappa$  [44]. Since the ratio  $\tau_{\text{rel}}/\tau_{\text{diff}}$  increases as  $\lambda$  grows,  
 102 one should check whether the inequality  $\tau_{\text{diff}} \gg \tau_{\text{rel}}$  holds for the largest characteristic scale,  
 103 that is, for the size of the membrane. Considering membranes with sizes  $\lambda = 100 - 500$  nm,  
 104 taking the viscosity  $\eta \sim 5 \cdot 10^{-3} \text{Pa} \cdot \text{s}$  and the lateral diffusivity  $D$  of proteins in the range  
 105  $1 - 10 \mu\text{m}^2/\text{s}$  [45, 46], one finds that the ratio  $\tau_{\text{diff}}/\tau_{\text{rel}}$  spans the values  $1 - 10^2$ , suggest-  
 106 ing that the dynamics of membrane fluctuations in living cells is faster than lateral particle  
 107 diffusion [44, 47, 48].

108 Membrane fluctuations are known to induce long-range effective interactions between in-  
 109 clusions within the membrane. These interactions can be conveniently studied in the weak  
 110 fluctuation regime, where quantitative analyses can be performed [31, 49–53]. It is of partic-  
 111 ular interest to investigate how these forces interplay with short-range forces to facilitate the  
 112 absorption of neighboring molecules by sorting domains.

113 Analytic expressions for membrane-mediated forces can be derived in various limit cases.  
 114 We are interested here in the interaction of a circular domain of size  $R$  with a molecule of  
 115 linear size  $a$  situated at a distance  $x$  from it. Approximating the domain boundary in zeroth  
 116 order as an infinite straight wall under the condition  $R \gg x \gg a$ , the effective potential energy  
 117 of the membrane-mediated interactions is given by:

$$U(x) = -Ak_B T \frac{a^2}{x^2} \quad (4)$$

118 where  $A$  is a dimensionless, increasing function of the relative rigidity  $\alpha = \kappa_1/\kappa_0$  (see Ap-  
 119 pendix A). Eq. (4) implies that  $U \sim Ak_B T$  near the surface of a domain. On the other hand,  
 120 the interaction potential between two inclusions mediated by the membrane fluctuations de-  
 121 cays as  $r^{-4}$  for distances  $r$  much larger than their sizes [31].

122 The process of lateral diffusion of a molecule situated near a circular sorting domain can  
 123 be described by the biased Brownian motion

$$\dot{\mathbf{r}} = -\beta D \nabla U(\mathbf{r}) + \xi,$$

124 where  $\beta = (k_B T)^{-1}$ . According to the fluctuation-dissipation theorem, the noise term  $\xi$  satis-  
 125 fies

$$\begin{aligned} \langle \xi_i(t) \rangle &= 0 \\ \langle \xi_i(t) \xi_j(t') \rangle &= 2D \delta_{ij} \delta(t - t'). \end{aligned}$$

126 It is worth observing here that in the limit of weak fluctuations, geometric effects caused by  
 127 the projection of the molecule's path can be neglected [54, 55]. Moreover, deviations of the

128 domain shape from circularity produce rapidly decaying higher multipole contributions that  
129 may be neglected in the main approximation.

130 The time-dependent density profile of a population of such diffusing molecules around a  
131 domain obeys the following diffusion equation

$$\partial_t n(\mathbf{r}, t) = \nabla \cdot [D(\nabla + \beta \nabla U)n(\mathbf{r}, t)] \quad (5)$$

132 where  $n$  is the two-dimensional molecular density. To study the growth of the domain, one  
133 can consider an isotropic, time-independent solution to Eq. (5). The assumption of isotropy  
134 is justified by the circular shape of the domain, while the approximate time independence is  
135 supported by the slow nature of the diffusion process. Consequently,  $n$  and  $U$  depend only on  
136 the distance  $r$  from the center of the domain. The explicit expression for  $n(r)$  is given by:

$$n(r) = n(R) \exp[\beta U(R) - \beta U(r)] + \frac{\Phi}{2\pi D} \int_R^r \frac{d\rho}{\rho} \exp[\beta U(\rho) - \beta U(r)], \quad (6)$$

137 where  $R$  is the radius of the domain and  $n(R)$  is the molecular density near the domain bound-  
138 ary. The potential  $U$ , induced by membrane fluctuations, is of the order of  $k_B T$  when  $r \sim R$   
139 and tends to zero as  $r$  grows (see Appendix A). Thus, for  $r \gg R$ , the solution (6) reduces to

$$n(r) = n(R) e^{\beta U(R)} + \frac{\Phi}{2\pi D} \ln \frac{r}{R}, \quad (7)$$

140 where  $\tilde{R} \sim R$ . For the attractive potential induced by membrane fluctuations,  $U < 0$ ,  $\tilde{R} > R$   
141 and  $\tilde{R} - R \sim R$ . The factor  $e^{\beta U(R)}$  in Eq. (7) is of order unity.

142 The density of molecules near the domain boundary is determined by the dynamic equi-  
143 librium of association and dissociation processes and can be expressed as

$$n(R) = n_0(1 + R_*/R), \quad (8)$$

144 where  $n_0$  is the equilibrium density near a straight boundary, and the  $R$ -dependent correction  
145 accounts for the effect of linear tension. This correction is directly related to the curvature  
146 of the domain boundary. The length  $R_*$  in Eq. (8) can be estimated to be of the order of a  
147 few molecular radii. Expression (8) allows to determine the critical radius  $R_c$ : by definition, a  
148 domain with radius  $R_c$  remains static, since the flux  $\Phi$  for such a domain is zero. Substituting  
149  $\Phi = 0$  and  $n(r) = n_L$  (where  $n_L$  is the concentration of the molecules far from the domains)  
150 into Eq. (7) yields:

$$\frac{R_*}{R_c} = \frac{n_L}{n_0} e^{-\beta U} - 1. \quad (9)$$

151 Since  $\exp(-\beta U) > 1$  for the attractive potential, we conclude from Eq. (9) that membrane-  
152 induced attraction reduces the critical radius. For domains larger than  $R_c$ , the correction re-  
153 lated to the linear tension can be neglected, resulting in  $n(R) \rightarrow n_0$ . Consequently, we find  
154 from Eq. (7):

$$n_L - n_0 e^{\beta U} = \frac{\Phi}{2\pi D} \ln \frac{L}{\tilde{R}}, \quad (10)$$

155 where  $L$  is a distance of the order of the separation between the domains. Since  $\exp(\beta U) < 1$   
156 for the attractive potential, we conclude from Eq. (10) that membrane-mediated attraction  
157 enhances the effectiveness of the clustering process, resulting in an increased flux  $\Phi$ .

158 The above relations show how forces mediated by membrane fluctuations affect the sorting  
159 process. Let us examine the effect of increasing membrane-mediated attraction (which can

160 be directly adjusted in numerical simulations by varying the relative rigidity  $\alpha = \kappa_1/\kappa_0$ .  
 161 As membrane-mediated attraction increases, the critical radius  $R_c$  of the domains decreases,  
 162 leading to a higher rate of production of germs of new sorting domains and, consequently,  
 163 an increased overall density  $N_d$  of sorting domains [37]. However, according to the balance  
 164 relation (1), this should concomitantly result in a lower  $\Phi$  and, in accordance with Eq. (10),  
 165 a lower  $n_L$ , which in turn reduces the rate of new domain generation. Between these two  
 166 opposing effects, the first is expected to dominate due to the high sensitivity of the process  
 167 of germ generation to the critical radius  $R_c$  [37]. Below, we present results from numerical  
 168 simulations that confirm this expectation.

169 It is worth observing here that in the stationary state, the density  $N_d$  of sorting domains  
 170 is self-consistently determined through the stationarity condition  $dN_d/dt = \phi/N_E$ , where  $N_E$   
 171 is the average number of molecules removed during an extraction event, since the rate of for-  
 172 mation of new domains  $dN_d/dt$  is in average equal to the rate of extraction events. [14, 15].  
 173 Starting from the regime of weak short-range interactions, the optimal density of sorting do-  
 174 mains  $N_{d,\text{opt}}$  determined by Eq. (2) can be reached either by increasing the short-range interac-  
 175 tion strength, or by reducing the critical radius by means of increased molecular rigidities  $\kappa_1$ .  
 176 Conversely, to increased molecular rigidities should correspond lower values of the optimal  
 177 short-range interaction strength.

### 178 3 Numerical results

179 To validate our theoretical predictions, we implemented a numerical scheme that generalizes  
 180 the lattice-gas model of molecular sorting introduced in Ref. [14]. This scheme shares several  
 181 features with the approach used in Ref. [56] to investigate the phase separation of rigid inclu-  
 182 sions in fluid membranes close to thermodynamic equilibrium, although we are studying here  
 183 an out-of-equilibrium state. We consider a fluctuating membrane described by a discretized  
 184 version of Helfrich Hamiltonian, on which inserted molecules laterally diffuse and aggregate.  
 185 The system is driven out of equilibrium by an incoming flux of molecules, which are randomly  
 186 attached at empty membrane sites with a rate  $\phi$  per unit area, and is maintained in a statistical  
 187 stationary state by the instantaneous removal of connected molecular domains that reach the  
 188 threshold number of molecules  $N_E$ . Consistently with our theoretical approach, simulations  
 189 are performed in the adiabatic regime.

Figure 1: Schematic representation of the discrete model of molecular sorting on a fluctuating membrane. The membrane (in blue) is described by its height relative to a reference plane (in black). Rigid molecules are inserted into vacant sites at a rate  $k_i$ , and connected domains containing more molecules than the threshold size  $N_E$  are extracted. The amplitude of membrane fluctuations is here amplified for the sake of clarity.

190 In our numerical scheme, the membrane configuration is described by the height  $u_i$  of its  
 191 points relative to a reference plane, which is discretized into a square lattice of  $L \times L$  sites,  
 192 see Fig. 1. To avoid boundary effects, periodic boundary conditions are applied. Each site  
 193 of the lattice can be occupied by at most one molecule. An occupation number  $n_i \in \{0, 1\}$   
 194 is associated to each site  $i$ . Sites with  $n_i = 0$  have the bending rigidity  $\kappa_0$ , while sites with  
 195  $n_i = 1$  have the rigidity  $\kappa_1$ . The corresponding Gaussian rigidities are assumed to be equal to  
 196  $-\kappa_0$  and  $-\kappa_1$ , respectively. To account for the short-range attractive force between membrane  
 197 inclusions we add to the discretized Helfrich energy of the membrane the nearest-neighbor  
 198 interaction energy

$$H_{\text{incl}} = -\frac{W}{2} \sum_{\langle i,j \rangle} n_i n_j \quad (11)$$

199 Membrane configurations are sampled using a Monte Carlo algorithm. After each Monte Carlo  
 200 sweep (MCS), steps involving molecule insertion, diffusion, and the extraction of domains of  
 201 size  $\geq N_E$  are performed. One MCS is taken as the time unit. The rate of molecule insertion per  
 202 empty site is denoted by  $k_I$ . The diffusion rate  $k_D$  of free molecules is measured as the ratio of  
 203 accepted diffusive jumps during one MCS (see Appendix B for additional details). Simulations  
 204 are performed with the realistic parameter values  $\kappa_0 = 10 k_B T$ ,  $N_E = 25$  [14–16, 57, 58], while  
 205  $k_I$  and  $k_D$  are kept much smaller than 1 in inverse MCS units, to ensure proper sampling of  
 206 membrane configurations within the adiabatic regime.

207 The average density  $\bar{\rho}$  of molecules in the stationary state satisfies the relation  $\bar{\rho} = \phi T$ ,  
 208 where  $T$  is the average time a particle spends on the membrane before being extracted, and  
 209  $\phi = k_I(1 - \rho)$  is the flux of incoming particles per site, if lengths are measured in units of the  
 210 lattice spacing [14, 59]. Therefore, in the statistically stationary state established at fixed  $\phi$ ,  
 211 the average density  $\bar{\rho}$  is a measure of the efficiency of the sorting process [14].

212 We investigated the behavior of the density  $\bar{\rho}$  as a function of the short-range interaction  $W$   
 213 and molecular rigidity  $\kappa_1$ . In Fig. 2, the resulting stationary densities are plotted as functions

Figure 2: Average density  $\bar{\rho}$  in the stationary state as a function of the short-range interaction strength  $W$ . The different curves correspond to different values of  $\alpha = \kappa_1/\kappa_0$ . In these simulations, the dimensionless flux is  $\phi/k_D = 10^{-5}$ . The optimal sorting region depends on both the short-range interaction and the rigidity of the biomolecules involved. To larger values of the relative molecular rigidity  $\alpha$  there correspond lower values of the optimal short-range interaction strength  $W_{\text{opt}}$  (arrows).

Figure 3: Characterization of the sorting process in the statistically steady state in terms of three key observables, measured from numerical simulations as functions of the short-range interaction strength  $W$ , for varying relative rigidities  $\alpha = \kappa_1/\kappa_0$ : (a) the critical radius  $R_c$  (estimated using the method described in Ref. [15]); (b) the number density  $N_d$  of supercritical domains; and (c) the average density of isolated molecules  $\bar{n}$ . Due to the logarithmic profile of the molecular density around sorting domains, the average density  $\bar{n}$  is close to  $n_L$ .

214 of the short-range interaction strength  $W$  for the fixed dimensionless flux  $\phi/k_D = 10^{-5}$  (see  
 215 Appendix B), with varying  $\alpha = \kappa_1/\kappa_0$ .

216 These numerical results confirm the theoretical prediction that membrane-mediated inter-  
 217 actions strongly influence the molecular sorting process, and that the optimal short-range  
 218 interaction strength  $W_{\text{opt}}$  decreases as the intensity of membrane-mediated interactions in-  
 219 creases, thus enhancing sorting efficiency in the biologically relevant regime of weak short-  
 220 range interactions.

221 To further validate the present theoretical scenario, we measured the critical size  $R_c$ , the  
 222 number density of sorting domains  $N_d$ , and the average density of isolated molecules  $\bar{n}$  (which  
 223 is approximately the same as  $n_L$ ) for varying values of  $W$  and  $\alpha$  (Fig. 3). Consistent with the  
 224 theoretical predictions, the critical size  $R_c$  decreases monotonically with both increasing  $W$   
 225 and  $\alpha$  (Fig. 3a), resulting in a higher sorting domain density  $N_d$  (Fig. 3b). This confirms that,  
 226 in the presence of membrane-mediated interactions, the optimal sorting-domain density  $N_{d,\text{opt}}$   
 227 is achieved at lower short-range interaction strengths  $W$ . As predicted, the increase in sorting-  
 228 domain density is reflected in a corresponding decrease in the average density of isolated  
 229 molecules  $\bar{n}$  (Fig. 3c).

## 230 4 Conclusions

231 The lipid membranes of endosomes, the Golgi apparatus, the endoplasmic reticulum, and  
 232 the plasma membrane play a fundamental role in sorting and distilling vital molecular factors,  
 233 acting as a natural realization of Szilard’s model of classical nucleation theory [37]. These deli-  
 234 ciate structures are inherently subject to thermally induced fluctuations. Previous studies have  
 235 shown that such fluctuations significantly contribute to the phase separation of rigid membrane  
 236 inclusions close to thermodynamic equilibrium [56]. Our analysis extends these findings to  
 237 the out-of-equilibrium scenario of molecular sorting, demonstrating that membrane-mediated  
 238 interactions can strongly enhance the molecular distillation of rigid inclusions, particularly, in  
 239 the biologically relevant regimes where short-range intermolecular attractive forces are rela-  
 240 tively weak. Our analysis suggests that thanks to membrane-mediated interactions, rigid  
 241 biomolecules can be sorted with high efficiency, despite their low-affinity interactions. Notably,  
 242 this effect, potentially crucial for biological systems, is observed in our numerical simulations  
 243 well below the threshold where phase separation occurs close to equilibrium [56]. This sug-

gests an important distinction between classical quasi-equilibrium phase separation processes and the role phase separation plays in out-of-equilibrium biological systems.

Molecular inclusions interact with the surrounding membrane due to both their rigidity and, possibly, non-zero intrinsic curvature [31,60] In this study, we have focused on the impact of rigidity on the molecular sorting process. In future work, we plan to investigate the complex interplay between rigidity and intrinsic curvature.

Our findings suggest that a key parameter controlling molecular sorting efficiency is the relative rigidity of the membrane and supermolecular domains, and that higher efficiency is achieved at intermediate values of this relative rigidity. These predictions may inspire future experimental investigations in real biological cells or in artificially prepared membranes.

## A Interaction of a molecule with a domain

In this section, we analyze the Casimir interaction between a circular domain of radius  $R$  and a single molecule of radius  $a \ll R$ , positioned at a distance  $x \gg a$  from it. We will calculate the interaction potential between the molecule and the domain.

In the absence of overhangs, the membrane can be parameterized in the Monge gauge [61], where each point on the membrane is defined by its displacement  $u(\mathbf{r}) = u(x, y)$  in the direction perpendicular to a reference plane  $\mathcal{S}$ . To second order in  $u$ , the Helfrich Hamiltonian, which provides the elastic energy of the deformed membrane, reads

$$\mathcal{H} = \int_{\mathcal{S}} dx dy \left\{ \frac{\kappa}{2} (\nabla^2 u)^2 + \bar{\kappa} [\partial_x^2 u \partial_y^2 u - (\partial_x \partial_y u)^2] \right\}, \quad (\text{A.1})$$

Here  $\kappa$  and  $\bar{\kappa}$  are bending and Gaussian rigidities, determined by an internal structure of the membrane. A surface-tension contribution to the energy could also be included, but it is assumed to be negligible and will not be taken into account.

Here we consider the interaction of a single molecule with a circular domain of molecules inserted into the membrane. When the molecule is positioned at the point  $\mathbf{r} = (x, y)$ , the interaction potential of the molecule with the domain is

$$U = B(\partial_x^2 \partial_{x'}^2 \mathcal{G}|_{x=x',y=y'} + 2\partial_x^2 \partial_{y'}^2 \mathcal{G}|_{x=x',y=y'} + \partial_y^2 \partial_{y'}^2 \mathcal{G}|_{x=x',y=y'}) + D(\partial_x^2 \partial_{y'}^2 \mathcal{G}|_{x=x',y=y'} - \partial_x \partial_y \partial_{x'} \partial_{y'} \mathcal{G}|_{x=x',y=y'}) \quad (\text{A.2})$$

where  $\mathcal{G}(\mathbf{r}, \mathbf{r}')$  is the contribution to the pair correlation function  $\langle u(\mathbf{r})u(\mathbf{r}') \rangle$  from the membrane displacement induced by the domain. The factors  $B, D$  in Eq. (A.2) are introduced via the phenomenological coupling energy of the molecule with the membrane, when the former is treated as a point-like object:

$$\delta \mathcal{H} = B(\nabla^2 u)^2 + D[\partial_x^2 u \partial_y^2 u - (\partial_x \partial_y u)^2] \quad (\text{A.3})$$

where the derivatives are evaluated at the position of the molecule. This expression is valid for fluctuations of  $u$  on scales much larger than  $a$ . The factors  $B$  and  $D$  are functions of the

278 rigidity and size of the molecule. We will make use of the fact that their expression for a disc  
 279 of radius  $a$  and rigidity  $\kappa = \kappa_1, \bar{\kappa} = -\kappa_1$ , inserted in a membrane of rigidity  $\kappa = \kappa_0, \bar{\kappa} = -\kappa_0$   
 280 is [52, 62]:

$$\begin{aligned} B &= \pi a^2 \kappa_0 (\kappa_1 - \kappa_0) \left( \frac{1}{(\kappa_1 + \kappa_0)} + \frac{1}{\kappa_1 + 3\kappa_0} \right) \\ D &= -\pi a^2 \frac{4(\kappa_1 - \kappa_0)\kappa_0}{\kappa_1 + 3\kappa_0}. \end{aligned} \quad (\text{A.4})$$

281 If the separation between the molecule and the domain boundary is much smaller than the  
 282 domain size  $R$ , the boundary can be approximated as a straight line. Therefore, we assume  
 283 that the domain occupies the half-plane  $x < 0$ . We also consider that the domain and the bulk  
 284 membrane have different bending and Gaussian rigidities,  $\kappa_1, \bar{\kappa}_1$  and  $\kappa_0, \bar{\kappa}_0$ , respectively. The  
 285 Hamiltonian of the system is then given by

$$\begin{aligned} \mathcal{H} &= \int_{\mathcal{D}_1} dx dy \left\{ \frac{\kappa_1}{2} (\nabla^2 u)^2 + \bar{\kappa}_1 [\partial_x^2 u \partial_y^2 u - (\partial_x \partial_y u)^2] \right\} \\ &+ \int_{\mathcal{D}_2} dx dy \left\{ \frac{\kappa_0}{2} (\nabla^2 u)^2 + \bar{\kappa}_0 [\partial_x^2 u \partial_y^2 u - (\partial_x \partial_y u)^2] \right\} \end{aligned} \quad (\text{A.5})$$

286 where  $\mathcal{D}_1$  is the left half-plane ( $x < 0$ ) and  $\mathcal{D}_2$  is the right half-plane ( $x > 0$ ).

287 Using linear response theory, we can derive an equation for the pair correlation function  
 288  $G = \langle u(\mathbf{r})u(\mathbf{r}') \rangle$ , entering Eq. (A.2). It is important to note here that, due to the system's  
 289 homogeneity in the  $y$  direction and its invariance under reflection  $y \rightarrow -y$ ,  $G$  is a function of  
 290  $|y - y'|$ . The resulting equations read

$$\begin{aligned} \nabla^4 G &= \frac{k_B T}{\kappa_1} \delta(x - x') \delta(y - y') \quad x < 0 \\ \nabla^4 G &= \frac{k_B T}{\kappa_0} \delta(x - x') \delta(y - y') \quad x > 0 \end{aligned} \quad (\text{A.6})$$

291 with boundary conditions

$$\begin{aligned} \partial_x (\kappa_1 \nabla^2 - \bar{\kappa}_1 \partial_y^2) G|_{x=0^-} &= \partial_x (\kappa_0 \nabla^2 - \bar{\kappa}_0 \partial_y^2) G|_{x=0^+} \\ (\kappa_1 \nabla^2 + \bar{\kappa}_1 \partial_y^2) G|_{x=0^-} &= (\kappa_0 \nabla^2 + \bar{\kappa}_0 \partial_y^2) G|_{x=0^+} \end{aligned} \quad (\text{A.7})$$

292 Observe that, due to the inhomogeneity of the Gaussian rigidity, the topological term involving  
 293 Gaussian curvature in the Hamiltonian cannot be neglected. This term contributes to the  
 294 boundary conditions (A.7) for the correlation function.

295 Due to translation invariance along the  $y$  direction, it is convenient to make use of the  
 296 Fourier transform

$$\hat{G}(x, x', q) = \int_{-\infty}^{+\infty} dy \exp[iq(y - y')] G(x, x', y - y'),$$

297 which is an even function of  $q$ . The solutions to Eqs. (A.6) and (A.7) for  $q > 0$  are

$$\hat{G}(x, x', q) = (A_0 + A_1 x) e^{qx} + \frac{k_B T}{4q^3 \kappa_1} (1 + q|x - x'|) e^{-q|x - x'|}$$

298 for  $x < 0$ , and

$$\hat{G}(x, x', q) = (B_0 + B_1 x) e^{-qx} + \frac{k_B T}{4q^3 \kappa_0} (1 + q|x - x'|) e^{-q|x - x'|}$$

299 for  $x > 0$ . The factors  $A_0, A_1, B_0, B_1$  must be determined from the continuity of  $\hat{G}$  and its deriva-  
 300 tive  $\partial_x \hat{G}$  at  $x = 0$  and from the boundary conditions (A.7), where  $\partial_r^2 \rightarrow -q^2$ ,  $\nabla^2 \rightarrow \partial_x^2 - q^2$ .  
 301 Assuming  $\bar{\kappa}_0 = -\kappa_0$  and  $\bar{\kappa}_1 = -\kappa_1$ , the correlation function for  $x, x' > 0$  is

$$\hat{G}(x, x', q) = \frac{k_B T}{4q^3 \kappa_0} \left[ (1 + q|x - x'|) e^{-q|x - x'|} - \frac{e^{-q(x+x')} (\kappa_1 - \kappa_0) ((3\kappa_1 + \kappa_0)q(x + x' + 2qxx') + 3\kappa_1 + 5\kappa_0)}{(3\kappa_1 + \kappa_0)(\kappa_1 + 3\kappa_0)} \right]. \quad (\text{A.8})$$

302 The second term in the square brackets determines the contribution  $\mathcal{G}$  to the correlation func-  
 303 tion induced by the domain.

304 In accordance with Eqs. (A.2,A.4,A.8) the interaction energy of the molecule with the  
 305 domain is

$$U(x) = -Ak_B T \frac{a^2}{x^2} \quad (\text{A.9})$$

306 where, letting  $\alpha = \kappa_1/\kappa_0$ ,

$$A = \frac{(\alpha - 1)^2 (3\alpha + 5)(5\alpha + 3)}{4(\alpha + 1)(\alpha + 3)^2 (3\alpha + 1)} \quad (\text{A.10})$$

307 The factor  $A$  is a monotonically increasing function of  $\alpha$  for  $\alpha > 1$ .

308 At large separations between the molecule and the domain, the size  $R$  of the domain be-  
 309 comes a relevant scale, and its boundary can no longer be treated as an infinite wall. In this  
 310 case, the interaction can be evaluated as [62]

$$U(x) = k_B T \frac{BD_R + B_R D}{2\pi^2 \kappa_0^2 x^4} = -\tilde{A} k_B T \frac{a^2 R^2}{x^4}, \quad (\text{A.11})$$

311 where

$$\tilde{A} = \frac{2(\alpha - 1)^2 (3\alpha + 5)}{(\alpha + 1)(\alpha + 3)^2}. \quad (\text{A.12})$$

312 Note that, by taking the appropriate limits, this expression reproduces previous analytical  
 313 results found in the literature [31, 52].

314 When considering a single molecule diffusing in the vicinity of a sorting domain, one of  
 315 the two regimes in Eq. (A.9) and Eq. (A.11) should be considered depending on the distance.  
 316 A convenient interpolation formula for the membrane-mediated interaction energy between a  
 317 molecule and a sorting domain of radius  $R$ , valid across different asymptotic regimes, is given  
 318 by the simplest two-point Padé approximant [63]

$$U(r) = -k_B T \frac{R^2}{r^2} \left[ \frac{Aa^2}{(r - R)^2 + a^2} + (\tilde{A} - A) \frac{a^2}{r^2} \right] \quad (\text{A.13})$$

319 where  $r = x + R$  is the distance from the molecule to the center of the domain. This reduces  
 320 to Eq. A.11 when  $r \gg R$ ,  $r \gg a$ , and to Eq. A.9 in the limit  $r \sim R$  and  $r - R \gg a$ , while also  
 321 avoiding the unphysical singularity at  $x = 0$ .

## 322 B Simulation protocol

323 Simulations are performed according to a protocol that employs a Monte Carlo technique  
 324 to sample Gibbs distributed configurations of the membrane, and a sub-lattice continuum  
 325 Langevin equation for particle dynamics within lattice cells. Each Monte Carlo sweep (MCS)  
 326 is executed as follows:

327 **Membrane:** Each site of the lattice is visited in random order, and a random displacement  
 328 of the height of the surface at that site is proposed, with uniform probability within an interval  
 329 of amplitude  $2l_0$  centered around the previous position. The move is accepted or rejected  
 330 according to the Metropolis criterion. The value of  $l_0$  is chosen to achieve an acceptance rate  
 331 of approximately 50% for the proposed moves.

332 **Diffusion:** After each membrane MCS, each lattice site  $i$  is visited in random order. If a  
 333 particle is present, the auxiliary variables  $x_i^{(t)}$  and  $y_i^{(t)}$  are updated according to the following  
 334 rule:

$$\begin{aligned} x_i^{t+1} &= x_i^t + \frac{F_x^t(x_i^t) + \sqrt{2\gamma k_B T} \eta^t}{\gamma} \\ y_i^{t+1} &= y_i^t + \frac{F_y^t(y_i^t) + \sqrt{2\gamma k_B T} \eta^t}{\gamma} \end{aligned} \quad (\text{B.1})$$

335 where  $\eta^t$  is a Gaussian noise with zero mean and variance 1, and  $F_x^t(x), F_y^t(y)$  are forces  
 336 acting on the molecule along the  $x$  and  $y$  directions at time  $t$  and position  $(x, y)$ . The constant  
 337  $\gamma$  plays the role of the friction coefficient in the Langevin equation and sets the average length  
 338 of the discrete steps of the auxiliary random walk. To ensure effective sampling, it is required  
 339 that  $\gamma \gg |F|$ . The coordinates  $(x_i^{(t)}, y_i^{(t)})$  can be interpreted as the sublattice position of the  
 340 molecule at site  $i$  at time  $t$ . The forces acting on the particle are evaluated as  $-\nabla U$ , where  $U$   
 341 is the discretized membrane energy, smoothed through a quadratic interpolation, in order to  
 342 achieve sub-lattice resolution. When  $x_i^t > h/2$  (respectively,  $< -h/2$ ), molecules are moved  
 343 one lattice site forward (respectively, backward) along the  $x$  direction. If the destination site  
 344 is occupied, the molecules are not moved, and their position is reset to  $x_i^t = h/2$  (respectively,  
 345  $-h/2$ ). The same procedure is applied in the  $y$  direction.

346 The sublattice Langevin dynamics for molecules is used to accurately capture the fast-  
 347 membrane-fluctuation regime. By selecting a sufficiently large value of  $\gamma$ , we ensure that the  
 348 particle samples a large-enough number of membrane configurations before reaching the jump  
 349 condition. For all the simulations performed, we set  $\gamma = 500 k_B T / h^2$ .

350 **Insertion:** A site is randomly selected, and if it is empty, a particle is inserted with probability  
 351  $k_I$ . As noted in Ref. [64], the more rigid are the molecules, the lower is their diffusivity. In  
 352 order to properly compare the results for  $\bar{\rho}$  obtained at different  $\kappa_1/\kappa_0$  ratios, it is important to  
 353 ensure that, although  $k_D$  is different for each  $\kappa_1/\kappa_0$ , the dimensionless flux  $r = \phi/k_D$  remains  
 354 the same. This is accomplished by measuring the diffusion rate  $k_D^{(t)}$  and the molecule density  
 355  $\rho^{(t)}$  at each MCS. These values are then used to adjust the insertion rate according to the  
 356 formula  $k_I^{(t)} = r k_D^{(t)} / (1 - \rho^{(t)})$ . This procedure guarantees that the dimensionless flux maintains  
 357 the assigned value  $r$ . Observe that since one MCS is taken as the time unit, the insertion  
 358 probability  $k_I$  per MCS can be interpreted as an insertion rate. Similarly, the diffusion rate  $k_D$   
 359 of free molecules—those jumping between two sites lacking occupied nearest neighbors—is  
 360 determined as the ratio of accepted diffusive jumps.

361 **Extraction:** if a connected component containing  $\geq N_E$  occupied sites is found in the system,  
 362 all particles this connected component are removed.
