Abstract

We investigate the superconducting properties of monolayer FeSe, both freestanding (ML FeSe) and on SrTiO₃ (STO), by simultaneously solving the Kohn-Sham Density Functional Theory and Bogoliubov–de Gennes equations. Our results demonstrate that the substrate profoundly alters both the normal-state and superconducting properties of FeSe. We identify proximity-induced superconductivity in the interfacial TiO₂ layer of STO, due to hybridization between Fe *d* and O *p* orbitals. This hybridization results in a fivefold increase in the superconducting gap width and confines superconducting states to the *M* point in the Brillouin Zone. This is in contrast to ML FeSe, where superconductivity emerges at both the Γ and *M* points. Furthermore, the substrate modifies the orbital character of the states responsible for superconductivity, which change from Fe *d*_{z²} in ML FeSe to Fe *d*_{xz}/*d*_{yz} in FeSe/STO. In both systems, we demonstrate an anisotropic superconducting gap with multiple coherence peaks, originating at different *k*-points in the Brillouin Zone. Additionally, in FeSe/STO, we identify emerging states unique to the superconducting phase arising from electron-hole hybridization at *M*, in agreement with experiments. Our findings highlight the decisive impact of substrate (hybridization, strain, charge transfer, magnetic order) on the superconducting properties of FeSe. We suggest potential pathways for engineering novel high-temperature FeSe-based superconductors by leveraging interfacial interactions in substrates with high electron affinity.

1 Introduction

Monolayer (ML) FeSe on SrTiO₃ (FeSe/STO) features high critical temperature ($T_C \sim 40\text{--}100$ K) making it appealing for both fundamental research and development of next-generation quantum devices [1–3]. The electronic dispersion of FeSe is highly sensitive to factors such as magnetic configurations, structural changes (strain) and the dielectric environment (doping and dipole interactions) [4]. The presence of a substrate affects all the above properties which, in turn, directly influence the superconducting pairing mechanism [5]. Experiments

8 on FeSe/STO proved the conventional BCS-like s -wave nature of the superconducting pairing
 9 potential [6]. Zhang *et al.* [7] reported two anisotropic superconducting gaps driven by Fe
 10 d_{xz}/d_{yz} (20 meV wide) and Fe d_{xy} (26 meV wide), reflecting the multiorbital nature of the
 11 Fermi surface and the orbital-dependent pairing in iron chalcogenides. Currently, it is still
 12 unclear whether FeSe/STO exhibits single or double coherence peaks [8], the interplay be-
 13 tween its magnetic and electronic properties is not fully understood, the agreement between
 14 theoretical predictions and experiments is incomplete, and the origin of high T_C is unknown.

15 Tight-binding models of FeSe ML and FeSe/STO successfully describe specific experiments
 16 but lack general applicability [1, 8] and are restricted to a normal state description. State-
 17 of-the-art theoretical studies [9–11] combine dynamical mean field theory (DMFT) and the
 18 quasiparticle self-consistent GW approximation to describe the superconducting instability of
 19 FeSe/STO from the spin and charge response of the system. These studies explain the de-
 20 pendence of the critical temperature on doping and Fe-O interaction. This method includes
 21 electron correlations and requires careful parameter tuning.

22 In this work, we simultaneously solve the Kohn-Sham Density Functional Theory (DFT)
 23 and Bogoliubov–de Gennes (BdG) equations [12, 13] to analyze and interpret both the nor-
 24 mal and superconducting states of ML FeSe and FeSe/STO. Our findings highlight the signifi-
 25 cant impact of the substrate on the superconducting (SC) phase of FeSe, and emphasize how
 26 interface-driven superconductivity can be leveraged to enhance superconductivity in FeSe. In
 27 the normal state, metallicity in ML FeSe arises from an electron pocket a M and a hole pocket
 28 along the $\Gamma - X$. In contrast, in FeSe/STO, the hole pocket shifts to lower energies within
 29 the valence band. This difference influences the mechanism behind superconductivity. In the
 30 superconducting phase, we predict proximity-induced superconductivity on the interfacial O
 31 atoms and a fivefold widening of the SC gap in FeSe/STO compared to ML FeSe. We elucidate
 32 the origins of superconducting coherence peaks in the superconducting density of states (SC-
 33 DOS) of both system, identifying univocally the real-space orbitals and momentum vector \mathbf{k}
 34 associated with these peaks. We characterize the Bogoliubov–de Gennes spectrum and predict
 35 an anisotropic, momentum-dependent superconducting gap $\Delta(\mathbf{k})$ for both system. We analyze
 36 the changes in electronic dispersion between freestanding ML FeSe and FeSe/STO, identifying
 37 the dominant roles of Fe d and O p orbitals in shaping the Fermi surface. We conclude that FeSe
 38 and FeSe/STO act as fundamentally different materials, as substrate hybridization, interfacial
 39 interactions and charge transfer play a crucial role in shaping the microscopic superconducting
 40 mechanism. This behaviour can be generalized to the whole family of iron pnictides. Substrate
 41 engineering presents a promising approach to design superconductors with enhanced T_C .

42 2 Structural properties

43 In the following, we focus on the tetragonal phase of ML FeSe, in view of comparing it with
 44 Fe/STO¹. The primitive unit cell of FeSe consists of two Fe and two Se atoms. The Fe atoms
 45 form two tetragonal sub-lattices, offset relative to each other [Fig. 1.(a)]. The Se atoms form
 46 tetrahedra centered on the Fe atoms. After structural relaxation, the lattice parameter of ML
 47 FeSe is 3.71 Å and the Se-Se distance is 1.44 Å. FeSe is usually grown by molecular beam
 48 epitaxy (MBE) on the TiO₂ terminated surface of STO [8]. For this reason, we first modeled
 49 STO as a six-layer slab and performed a full relaxation (atoms and unit cell), obtaining a
 50 lattice constant of 3.92 Å. The atomic positions of the FeSe/STO heterostructure were then
 51 relaxed while keeping the STO lattice fixed, resulting in 5.7% strain on FeSe ML. The FeSe/STO
 52 heterostructure was constructed by placing the bottom Se atom of FeSe directly above the top

¹While single crystal FeSe undergoes a tetragonal-to-orthorhombic phase transition below 90K [5], we expect that the symmetry of the STO surface (D_4) will stabilize the tetragonal FeSe phase of FeSe in FeSe/STO [5]

53 Ti atom of the STO substrate. After relaxation, the Se-Ti distance was 2.95 Å [Fig. 3.(a)].

54 2.1 Magnetic instabilities

55 FeSe, both in its bulk and ML forms, exhibits a complex energy landscape characterized by
 56 multiple competing magnetic configurations. The lowest-energy magnetic state of bulk FeSe
 57 is theoretically predicted to be the staggered dimer phase [14]. However, long-range mag-
 58 netic order is not observed in experiments [15, 16]. Indeed, bulk FeSe is a nematic quantum-
 59 disordered paramagnet, interpolating between the checkerboard antiferromagnetic (CB-AFM)
 60 and stripe AFM phases, both in the low ($T = 4$ K) and high temperature ($T = 110$ K) regimes [17].
 61 For bulk and ML FeSe, we computed first-principles total energies of various magnetic config-
 62 urations (Appendix A). In both cases, we found three low-energy competing magnetic con-
 63 figurations: staggered trimer, staggered dimer, and single stripe, followed by two CB-AFM
 64 phases (in- and out-of-plane) with similar total energies, approximately 68 meV above the
 65 lowest-energy configurations. We find that only the band structure of the out-of-plane CB
 66 phase [Fig. 1.(a)] resembles the ARPES electronic dispersion [4, 18]. For this reason, we focus
 67 on the CB phase despite its higher total energy compared to the other phases.

68 2.2 Normal state electronic properties

69 The normal state band structure of ML FeSe features an electron pocket at M , a hole pocket
 70 along the $\Gamma - X$ high-symmetry line, and a relative maximum in the highest occupied valence
 71 band along the $\Gamma - M$ line [Fig. 1.(b)]. Analysis of the Mulliken populations [19] reveals that
 72 FeSe acquires 0.13 electrons (per unit cell) from STO in the FeSe/STO heterostructure. As a
 73 result, the hole pocket along the $\Gamma - X$ direction is pushed below the Fermi-level, and the top
 74 valence band becomes flatter [Fig. 3.(b)].

75 The origin of metallicity in FeSe changes due to the interaction with the substrate: in
 76 the freestanding ML, metallicity is associated with the electron and a hole pocket, while in
 77 FeSe/STO only to the electron pocket at M . Analysis of the Fermi surfaces (Fig. 16) facilitate
 78 the visualization of these concepts: In FeSe ML, the hole pocket along $\Gamma - X$ is clearly visible
 79 in Fig. 16.(a), while the relative maxima along $\Gamma - M$ lies tens of meV lower in energy. In
 80 FeSe/STO, instead, the hole pocket near Γ disappears. At M , the electron pocket of FeSe/STO
 81 has a more pronounced hyperbolic shape with respect to FeSe ML [Fig. 16.(b)]. This will have
 82 consequences in the superconducting behaviour of the two materials.

83 Orbital projected band structures of FeSe and FeSe/STO [Fig. 2] show that the orbitals as-
 84 sociated to the electron pocket at M are Fe d_{xz} , d_{yz} , and, to a lesser extent, d_{xy} . In FeSe/STO
 85 [Fig. 15] a hole pocket associated to interfacial O p_x/p_y states emerges at M . In the supercon-
 86 ducting phase of FeSe/STO, the Fe d states hybridize with O p_x and O p_y and are responsible
 87 for the opening of the superconducting gaps at M , as predicted by Acharya et al. [9–11].

88 2.3 Superconducting state

89 In order to model the superconducting phase, we solve the SIESTA-BdG equations using the
 90 *fixed- Δ* approach [12]. We initialize the superconducting pairing potential $\Delta(\mathbf{r})$ in the *super-*
 91 *conducting strength representation*. In this approach, the pairing potential is expressed, in real
 92 space, via a superconducting strength parameter $\bar{\Delta}$.

93 In ML FeSe, we initialize $\Delta(\mathbf{r})$ with spheres centered on the Fe atoms, each with $\bar{\Delta} = 15$ meV
 94 [Fig. 1.(a)]. The BdG spectrum [Fig. 1.(b, c)], the SC-DOS $\rho(\varepsilon)$ and anomalous DOS $\chi(\varepsilon)$
 95 [Fig. 1.(d)] reveal several superconducting gaps/coherence peaks at energies ± 1.8 (Δ_1), ± 5
 96 (Δ_2), and ± 6.4 meV (Δ_3). The orbital projected SC-DOS [Fig. 1.(f)] shows that the supercon-
 97 ducting states are mostly dominated by the Fe $3d_{z^2}$ and, to a minor extent, by $3d_{xz}$ and $3d_{yz}$

98 orbitals. We identify the nature of the coherence peaks from the superconducting [Fig. 1.(d)]
 99 and orbital-projected normal state (Fig.2) band structures: The Δ_1 coherence peaks originate
 100 from Fe d_{z^2} along $X - M$ (close to M) and to d_{xz}/d_{yz} along $\Gamma - X$ [Figs. 2.(a, b, c)]. Δ_2
 101 originates from Fe d_{xz} and d_{yz} along $M - \Gamma$ close to M [Fig. 2.(a, b)]. Δ_3 originates from
 102 Fe d_{z^2} along $\Gamma - M$ close to Γ [Fig. 2.(c)]. The Δ_1 and Δ_2 peaks exhibit strong electron-hole
 103 coupling, as evidenced by the band inversion between electrons (red) and holes (blue) at the
 104 corresponding gap [Fig. 1.(d)]. From the band structure, we observe a strong anisotropy in
 105 the momentum-resolved superconducting gap structure, i.e., $\Delta(\mathbf{k}_1) \neq \Delta(\mathbf{k}_2)$. We note that
 106 the type of Fe orbitals associated with superconductivity and the nature of superconductivity
 107 in bulk FeSe differs from ML FeSe: We have recently showed [12] that the superconducting
 108 gap of bulk FeSe is V-shaped, and is due to Fe d_{xz} and d_{yz} only, in agreement with experi-
 109 ments [20]. FeSe ML, instead, features a U-shaped gap with multiple coherence peaks, mostly
 110 due to d_{z^2} and, in minor part, to d_{xz} and d_{yz} orbitals.

111 FeSe/STO exhibits three pronounced peaks at ± 8 (Δ_1), ± 14.3 (Δ_2), and ± 20 meV (Δ_3)
 112 in the SC-DOS [Fig. 3.(e)]. The superconducting band structure [Fig. 3.(d)] shows several
 113 gaps of different sizes near M , along the $M - X$ and $M - \Gamma$ directions, demonstrating that
 114 $\Delta(\mathbf{k})$ is anisotropic. The normal-state band structure [Fig. 3.(b)] and the projected SC-DOS
 115 [Fig. 3.(g)] allow us to attribute the Δ_1 and Δ_2 peaks/gaps to the STO substrate and, more
 116 specifically, to the interfacial O p_x and p_y states [Figs. 15.(g,h)]. Therefore, we deduce that su-
 117 perconductivity has been induced by proximity on the oxygen atoms. The Δ_3 peak is, instead,
 118 due to Fe and originates along the $M - \Gamma$ line close to M . By comparing with FeSe ML, we
 119 deduce that the Fe-related SC-gap at M broadens and changes in orbital character from d_{z^2} to
 120 d_{xz} and d_{yz} , [Fig. 3.f] in FeSe/STO due to coupling with the substrate. The hybridization be-
 121 tween FeSe and the substrate, combined with particle-hole symmetry, leads to the emergence
 122 of new bands in the BdG spectrum [Figs. 3.(c,d)] that are not present in the normal state dis-
 123 persion [Figs. 3.(b)]. These new bands are at Γ (~ 250 meV below E_F), and M ($\sim 15-30$, 70
 124 and ~ 180 meV below E_F) originating from the hybridization of Fe d_{z^2} and O p_z (at Γ) and
 125 Fe d_{xz} and d_{yz} with O p_x and p_y (at M). The energy range of these bands corresponds to
 126 the experimentally observed “replica bands” [21]. In our simulations, replica bands originate
 127 from: (i) the superconducting pairing potential which couples the interfacial region between
 128 FeSe and STO, and (ii) particle-hole symmetry which mirrors the normal-state conduction
 129 states in the valence manifold. Our results qualitatively agree with ARPES measurements of
 130 FeSe/STO [1, 2, 8]. Differences might be due to the semi-phenomenological nature of the
 131 SIESTA-BdG method: the initialization of the pairing potential results in an energy shift of the
 132 coherence peaks (Appendix B).

133 3 Conclusion

134 In this study, we investigated the superconducting properties of ML FeSe, employing a com-
 135 bined Kohn–Sham and Bogoliubov–de Gennes approach. We analyzed two cases: freestanding
 136 FeSe (ML FeSe) and FeSe on a TiO_2 -terminated STO substrate (FeSe/STO).

137 For both systems, we predicted an anisotropic superconducting gap $\Delta(\mathbf{k})$ [Figs. 3.(d)
 138 and 1.(d)]. We identified the nature of the superconducting coherence peaks and attributed
 139 their origin to specific regions in the Brillouin Zone: In freestanding FeSe, superconductivity
 140 is due to states around Γ and M points. In FeSe/STO, superconductivity originates from states
 141 around the M point only.

142 In addition, we identified the specific atoms and orbitals that are responsible for super-
 143 conductivity: We observed a change in the orbital character of the Fe states responsible for
 144 superconductivity from d_{z^2} (ML FeSe) to d_{xy}/d_{yz} (FeSe/STO). In FeSe/STO, Fe d and O p

145 orbitals strongly hybridize near the Fermi energy at the M point [Figs. 3.(b)] giving rise to
146 two coherence peaks ($\Delta_{1/2}$, mostly contributed by O) and a higher-energy one (Δ_3 , mostly
147 contributed by Fe). Remarkably, we observed proximity-induced superconductivity in the in-
148 terfacial TiO_2 layer.

149 Our analysis of the normal-state band structure of the two materials allowed us to shed light
150 on the different mechanisms behind their superconductivity: In ML FeSe, metallicity originates
151 from an electron pocket at M and a hole pocket along the $\Gamma - X$ line. In FeSe/STO, instead,
152 the hole pocket shifts to lower energies in the valence band. Therefore, the superconducting
153 mechanism is intrinsically different in two cases: In ML FeSe, Cooper pairs can either form at
154 $\sim \Gamma$ and $\sim M$ (difference between electron and hole crystal momentum $Q = 0$), or can scatter
155 between M and Γ ($Q \neq 0$). In FeSe/STO, instead, Cooper pairs formation is only possible at
156 M ($Q = 0$).

157 In both ML FeSe and FeSe/STO, we found multiple competing magnetic configurations. In
158 this work, we focused on the checkerboard antiferromagnetic phase because its band structure
159 best resembles ARPES measurements [18]. The impact of different magnetic configurations
160 on the superconducting phase remains an open question, with the possibility that supercon-
161 ductivity may be favored in a specific direction when using the single stripe configuration with
162 different spin alignments along the x and y axes. Future studies could investigate the super-
163 conducting state under different magnetic configurations to provide deeper insights into its
164 behavior, or explore the potential for topological superconductivity in FeSe systems coupled
165 with magnetic impurities and strong spin-orbit coupling, such as the recently observed zero
166 energy states at the edges of line defects in Fe(Se, Te) [22].

167 Our findings emphasize the role of hybridization with the substrate in determining the
168 superconducting properties of FeSe. Hybridization between Fe and the substrate triggers
169 proximity-induced superconductivity in STO. We suggest that heterostructures consisting of
170 FeSe and substrates, including elements with high electron affinity, will promote charge trans-
171 fer and facilitate Cooper pair formation in the substrate, opening the way to engineering novel
172 FeSe-based superconductors operating at high temperatures.

173 4 Methods

174 4.1 First-principles ground state simulations

175 All simulations were performed using the SIESTA method [13, 23], with the PBE [24] func-
176 tional, norm-conserving pseudopotentials from the Pseudo-Dojo database [25], and the default
177 SIESTA double- ζ polarized (DZP) basis set with an orbital cutoff radii of 272 meV. Simulations
178 were converged for a mesh-cutoff of 1300 Ry. In FeSe/STO we account for the correlation
179 effects between Fe and the interfacial oxygen atoms by applying a Hubbard correction U of
180 0.1 eV to the Fe d states [26, 27]. This value of U allows us to reproduce reasonably the band
181 dispersion observed in ARPES [3, 17], in particular the position of the highest occupied state
182 at Γ , as illustrated in Fig. 14). All calculations include SOC.

183 To solve the KS-equations, we employed a $101 \times 101 \times 1$ and $16 \times 16 \times 1$ k-grid for ML FeSe
184 and FeSe/STO, respectively. The Fermi-Dirac occupation function was smoothed out using an
185 electronic temperature of 10 meV in the normal state for both freestanding FeSe and FeSe/STO.
186 This value has been lowered to 0.1 meV for the superconducting state simulations to ensure
187 that the broadening of the electronic states is well below the size of the superconducting gap.
188 The crystal structures were relaxed with a maximum force tolerance of $0.005 \text{ eV}/\text{\AA}$.

189 4.2 SIESTA-BdG method

190 The superconducting properties were modeled using the SIESTA-BdG method [12]. In this
191 approach, a semi-empirical superconducting pairing potential is introduced on top of the
192 self-consistent Kohn-Sham Hamiltonian describing the normal state. We used the *fixed- Δ*
193 method with the superconducting pairing potential initialized in real space (*superconduct-*
194 *ing strength representation*) as touching spherical hardwells. We used hardwells with radius
195 $r = 1.32 \text{ \AA}$ ($r = 1.39 \text{ \AA}$) and strength $\bar{\Delta} = 15.0 \text{ meV}$ ($\bar{\Delta} = 73.0 \text{ meV}$) around the Fe atoms
196 for ML FeSe (FeSe/STO). We used a radius of $r = 1.5 \text{ \AA}$ and $\bar{\Delta} = 11.0 \text{ meV}$ for the interfacial
197 oxygen atoms. For a discussion on the initialization of different pairing potential see Support-
198 ing Information B. The superconducting DOS were sampled with a uniform $350 \times 350 \times 1$ and
199 $301 \times 301 \times 1$ k-grid, and refined with one iteration of the adaptive-grid scheme with a $3 \times 3 \times 1$
200 subgrid for ML FeSe and FeSe/STO, respectively.

221 A Magnetic order

222 Over the last decade, the ground state of FeSe has been hotly debated in the literature. Mag-
223 netic frustration and spin fluctuations make it difficult to describe this system with the Heisen-
224 berg or Ising models. Recently, *Glasbrenner et al.* [14] performed a detailed analysis, based
225 both on first principles and model calculations establishing the Staggered Dimer (SD) as the
226 most stable configuration for this system. Our first-principles *ab-initio* analysis confirms their
227 result. In Fig. 4 we show the computed total energies for the Single Stripe (SS), Staggered
228 Trimer (ST), Staggered Dimer, in-plane (IP) and out-of-plane (OOP) CheckerBoard (CB), Fer-
229 roMagnetic (FM) and non magnetic (NM) configurations. We report the difference in total

230 energies ΔE with respect to the ground state (E_{min}) in Fig.s 4 and 5 and Table 1.

231 Two different basis sets were tested: Double-Zeta Polarized (DZP) with orbital-confining
232 cutoff radii (PAO.EnergyShift) of 272 meV and 25 meV. The first choice leads to physically
233 correct energetic ordering, and therefore our calculations are performed with this basis set.

234 The low-energy magnetic configurations for ML FeSe are ST, SS, and SD, with the ST only
235 0.231 meV below the SD. This energy difference is below the 0.5 meV/Fe accuracy of our
236 simulations, hence, we conclude that the three configurations are iso-energetic. We report
237 our results in Fig. 5 and Table 1.

Table 1: Difference in total energies $\Delta E = E - E_{min}$, of ML FeSe and FeSe/STO with different magnetic configurations. The minimal energies are highlighted in bold.

238 B Initialization of the Pairing Potential and Its Impact on the Su- 239 perconducting Properties

240 In the SIESTA-BdG method, one can employ different approaches for solving the BdG equations
241 and initializing the pairing potential Δ [12]. We explored multiple initialization schemes for
242 the pairing potential in both ML FeSe and FeSe/STO. In the main text, we focus on results ob-
243 tained using the *fixed- Δ* method to solve the SIESTA-BdG equations, initialized within the *su-
244 perconducting strength representation*. The *fixed- Δ* algorithm solves the Bogoliubov-de Gennes
245 equations ensuring self-consistency in the normal Hamiltonian and density while holding Δ
246 constant during the SIESTA-BdG scf steps. At every scf step the normal state Hamiltonian, the
247 normal and the anomalous densities are updated. The *superconducting strength representation*
248 initializes Δ in real space by specifying an initial guess for the pairing strength, $\bar{\Delta}$ (when no
249 risk of confusion arise, we simply write Δ).

250 For ML FeSe, we analysed the shape and magnitude of the SC-DOS $\rho(\epsilon)$ while varying
251 the initial value of $\bar{\Delta}$. As shown in Fig. 6, $\rho(\epsilon)$ is zero for $\bar{\Delta} = 0$, indicating the absence
252 of superconductivity. A transition from a non-gapped to fully gapped SC-DOS occurs as $\bar{\Delta}$
253 increases from 3 to 5 meV. Namely, $\bar{\Delta} < 5$ meV is too small to describe superconductivity
254 in ML FeSe. For $\bar{\Delta} = 5$ meV, the double peaks around ± 8 meV merge into a single peak.
255 Further increases in $\bar{\Delta}$ result in broader coherence peaks, reflecting the enhanced value of the
256 superconducting pairing potential. Experimentally, different values for the superconducting

257 gap width have been reported, with $\bar{\Delta} = 15$ meV in [8]. The BdG spectrum and SC-DOS
 258 (Figs. 7 and 6) does not, qualitatively, change for $\bar{\Delta}$ close to 15 meV. Therefore, we employed
 259 $\bar{\Delta} = 15$ meV for the SIESTA-BdG simulations presented in the main text.

260 For FeSe/STO, the interpretation of the SC-DOS is more complex. Our results indicate that
 261 only the states near the FeSe/STO interface contribute significantly to $\rho(\varepsilon)$ close to the Fermi
 262 level, regardless of the spatial initialization of the pairing potential. In order to assess this
 263 statement, we first initialize the pairing potential $\bar{\Delta}$ uniformly across the unit cell (Fig. 9) with
 264 values ranging from 0 to 24 meV. The SC-DOS is metallic for $\bar{\Delta} = 0$. As $\bar{\Delta}$ increases, two peaks
 265 are clearly distinguishable and their separation widens. At $\bar{\Delta} = 0$ meV, we observe a pair of
 266 coherence peaks at ± 4.5 meV, which we attribute to the gaps in flat degenerate bands near the
 267 Fermi level in the normal state of FeSe/STO [Fig. 3.(b)]. These peaks primarily originate from
 268 Fe d orbitals. As $\bar{\Delta}$ increases, a second pair of coherence peaks emerges starting at $\bar{\Delta} = 6$ meV.
 269 This second pair, associated with interfacial O p -orbitals, becomes broader with increasing $\bar{\Delta}$,
 270 while the first pair remains unchanged. Thus, the constant initialization of the pairing poten-
 271 tial indicates that both Fe and oxygen play a role in the superconducting coupling, although
 272 the exact peak positions are not quantitatively accurate. Furthermore, the SC-DOS does not
 273 completely drop to zero regardless of the value of $\bar{\Delta}$ while the anomalous DOS does. We inter-
 274 pret this behavior as follows: the first pair of coherence peaks arises from intrinsic electronic
 275 properties (coupling to STO), while the second is driven by the superconducting pairing po-
 276 tential, as evidenced by the trends in $\chi(\varepsilon)$. The BdG spectrum near the high-symmetry point
 277 M (Fig. 8) provides further insights. Along the $M - X'$ path (left) and the $M - X$ path (right),
 278 we observe a widening separation between electron and hole states as $\bar{\Delta}$ increases, except for
 279 states near the Fermi level. Notably, a gap-closing feature appears along the $M - X'$ path,
 280 which is absent along $M - X$. This suggests a breaking of inversion symmetry in the system.
 281 A value of $\bar{\Delta} = 24$ meV is not sufficient to fully open the gap for FeSe/STO. Our tests indicate
 282 that at least a value of 45 meV is needed. For the reasonings above, we initialized the pair-
 283 ing potential $\bar{\Delta}$ only on the Fe atoms of the ML and the interfacial oxygen atoms. We tested
 284 that, qualitatively, no differences arise if the superconducting pairing potential is initialized
 285 uniformly across the unit cell or only on the Fe and interfacial Oxygen atoms. We also tested
 286 the case where the superconducting pairing potential is initialized as touching spheres on the
 287 Fe atoms (Fig. 10).

288 For FeSe/STO, we report the SC-DOS and anomalous DOS for different values of $\bar{\Delta}$ from
 289 0 meV up to 300 meV, with the superconducting pairing initialized on the Fe interfacial oxygen
 290 atoms (Figs. 11 and 12). These results show that for a higher value $\bar{\Delta}$ the SC-DOS becomes
 291 gapped.

292 C Supplementary Electronic Structure Analysis of ML FeSe and 293 FeSe/STO

294 In this section, we present supplementary figures that support the discussion in the main text.
 295 We compute the orbital-projected band structure of ML FeSe (Fig. 13) and FeSe/STO (Fig. 15).
 296 We show the Fermi surfaces of ML FeSe and FeSe/STO (Fig. 16). We examine the changes in
 297 the electronic dispersion of FeSe/STO as a function of the Hubbard U parameter (Fig. 14). We
 298 compare our results with ARPES data [8] and employ a value of $U = 0.1$ eV for the simulations
 299 performed in the main text.

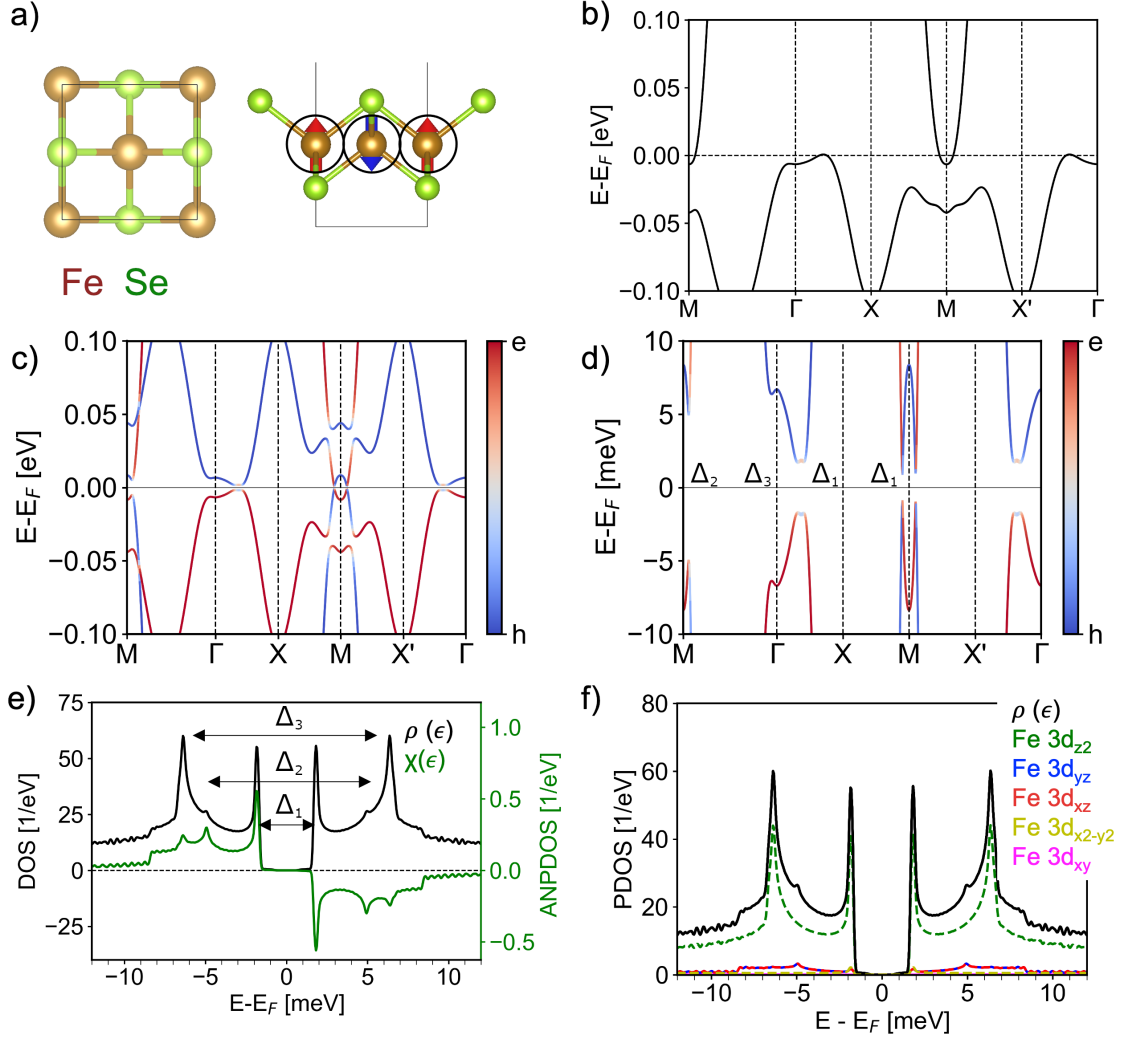

Figure 1: ML FeSe in the CB-AFM magnetic phase. (a) Top and side view of a unit cell of ML FeSe, with red and blue arrows representing spin directions and black circles illustrating the initialization of the superconducting pairing potential. (b) Normal state band structure. (c) Superconducting band structure projected on the electron (red) and hole (blue) components of the BdG spectrum. In (d) we report a narrower energy range around the SC gap. (e) SC-DOS ($\rho(\epsilon)$, black) and anomalous SC-DOS ($\chi(\epsilon)$, green) exhibiting superconducting gaps with widths $\Delta_1 = 3.6$, $\Delta_2 = 10.0$, and $\Delta_3 = 12.8$ meV. (f) SC-DOS projected over Fe orbitals.

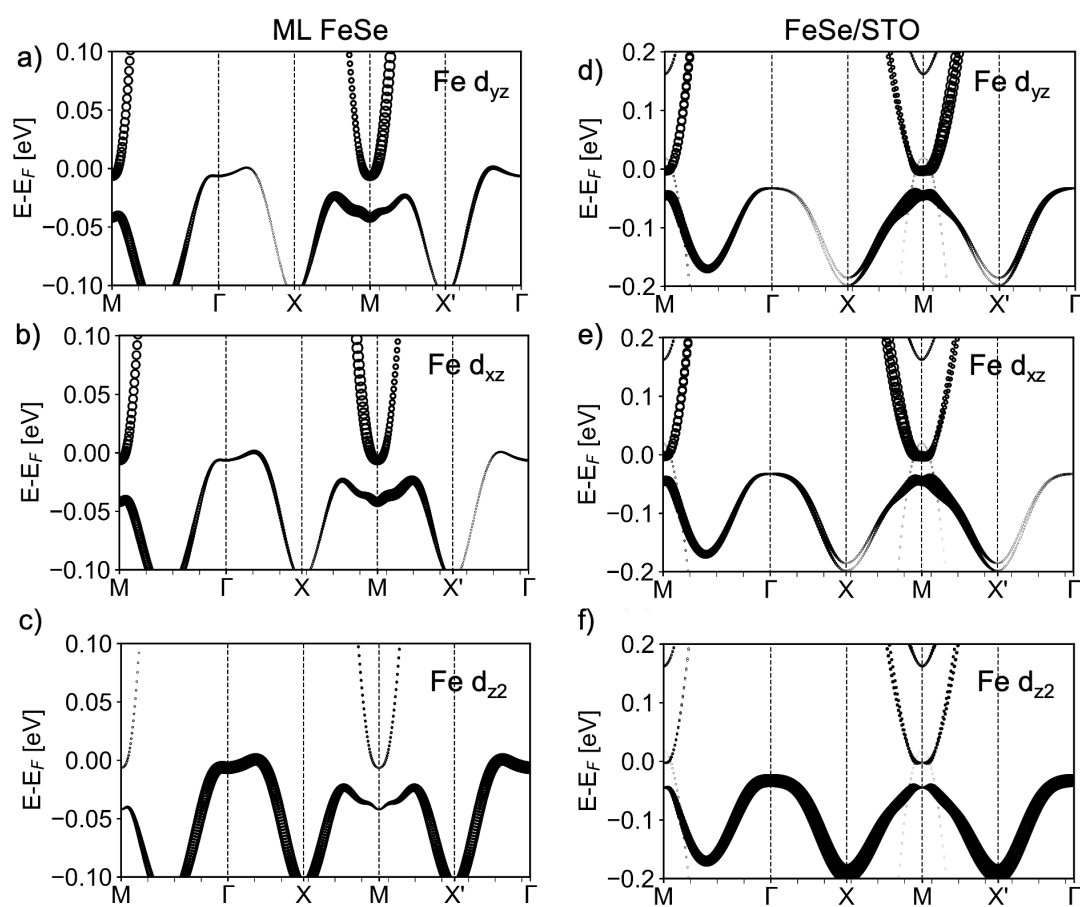

Figure 2: Normal state electronic band structures of (a-c) FeSe ML and (d-f) FeSe/STO projected on selected Fe orbitals. The projection over all orbitals is reported in Appendix Figs. 13 and 15

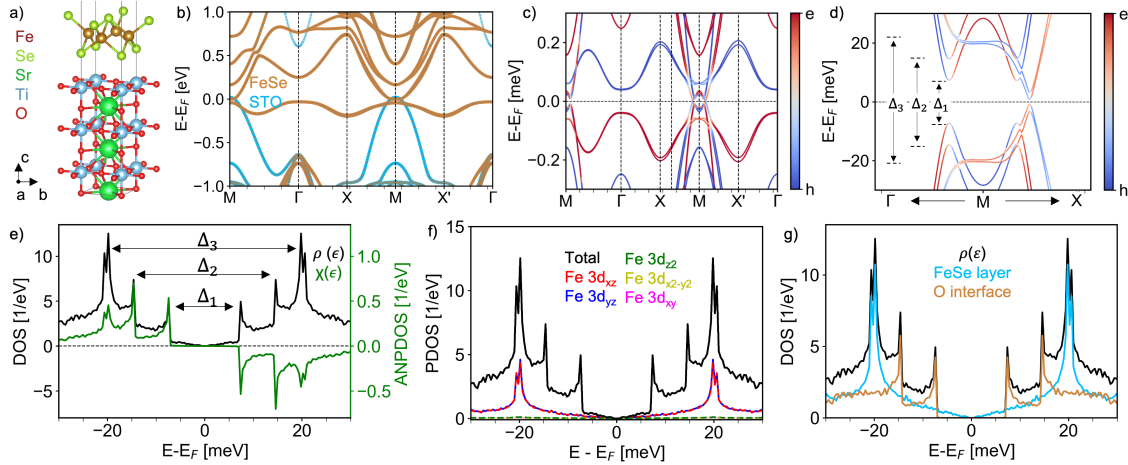

Figure 3: FeSe/STO with a TiO_2 -terminated surface, FeSe is in the checkerboard AFM magnetic phase: (a) atomistic model (side view). (b) Electronic band structure projected on FeSe (light brown) and STO (light blue). (c,d) Superconducting band structure in two different energy ranges. The color scheme highlights contributions from electron-like (red) and hole-like (blue) components of the BdG spectrum. (e) SC-DOS ($\rho(\varepsilon)$, black) and anomalous SC-DOS ($\chi(\varepsilon)$, green) with superconducting gap widths $\Delta_1 = 16.0$, $\Delta_2 = 28.6$, and $\Delta_3 = 40.0$ meV. (f,g) Total (black) and projected SC-DOS over (f) orbitals, and (g) FeSe layer (light brown) and interfacial O atoms (light blue).

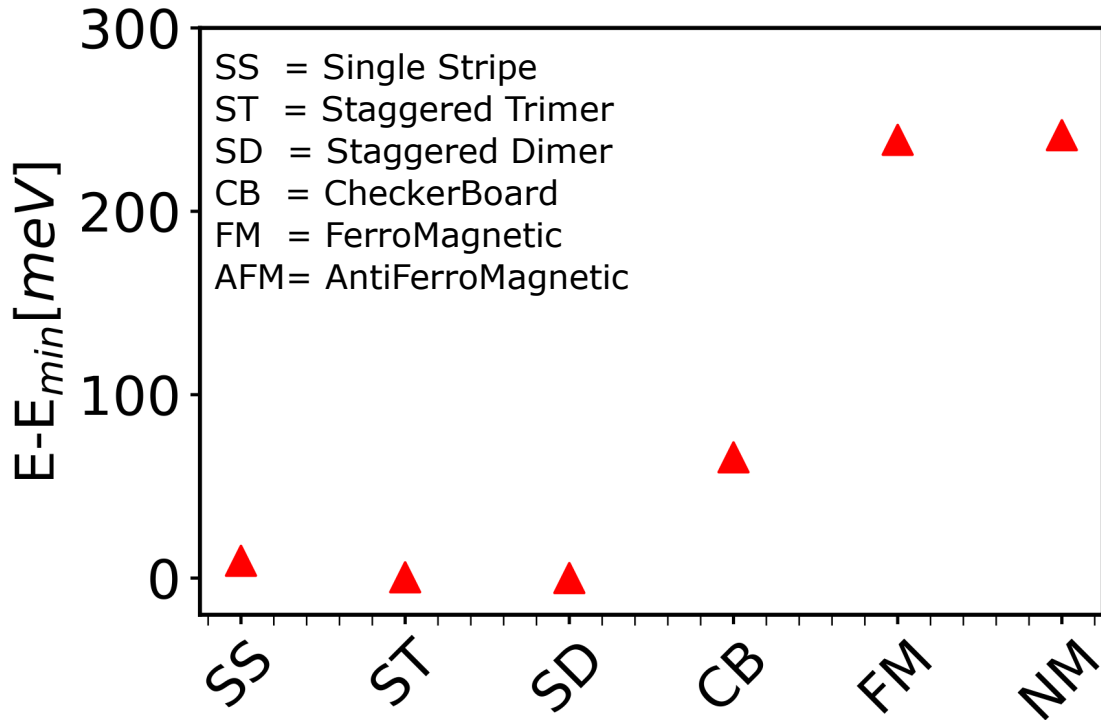

Figure 4: Energetic magnetic ordering for FeSe bulk. The lowest energy magnetic state is the Staggered Dimer configuration.

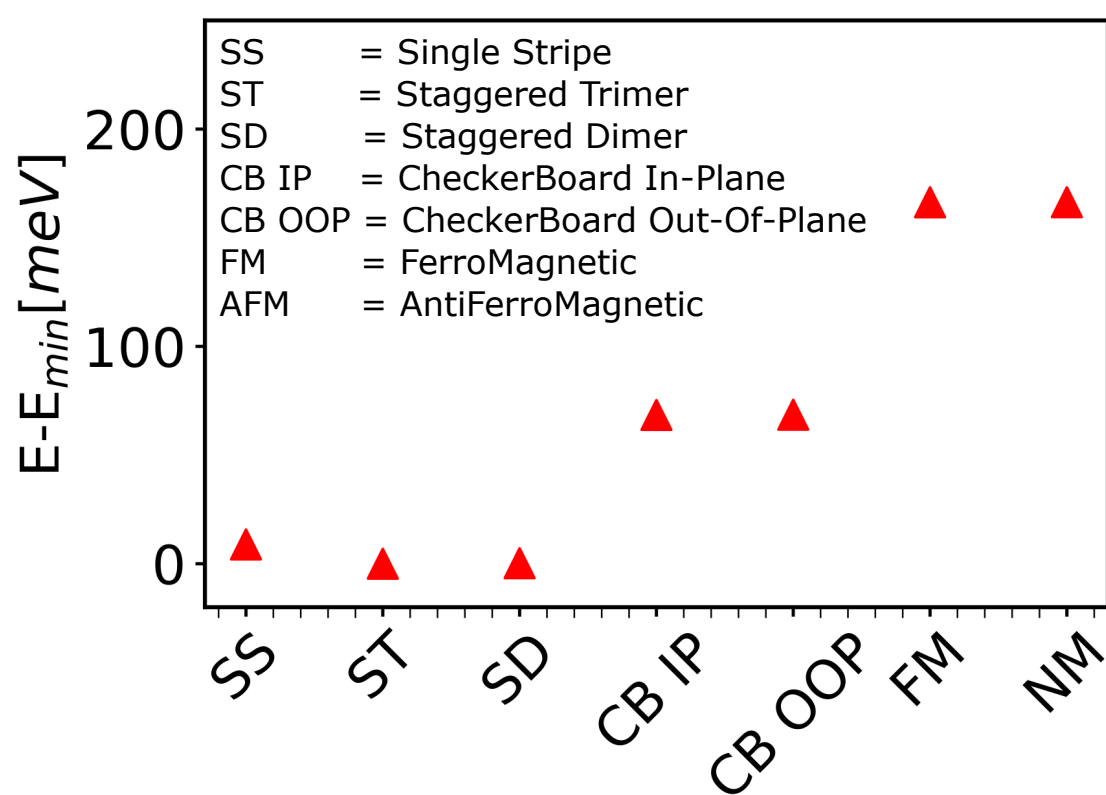

Figure 5: Energetic magnetic ordering for ML FeSe.

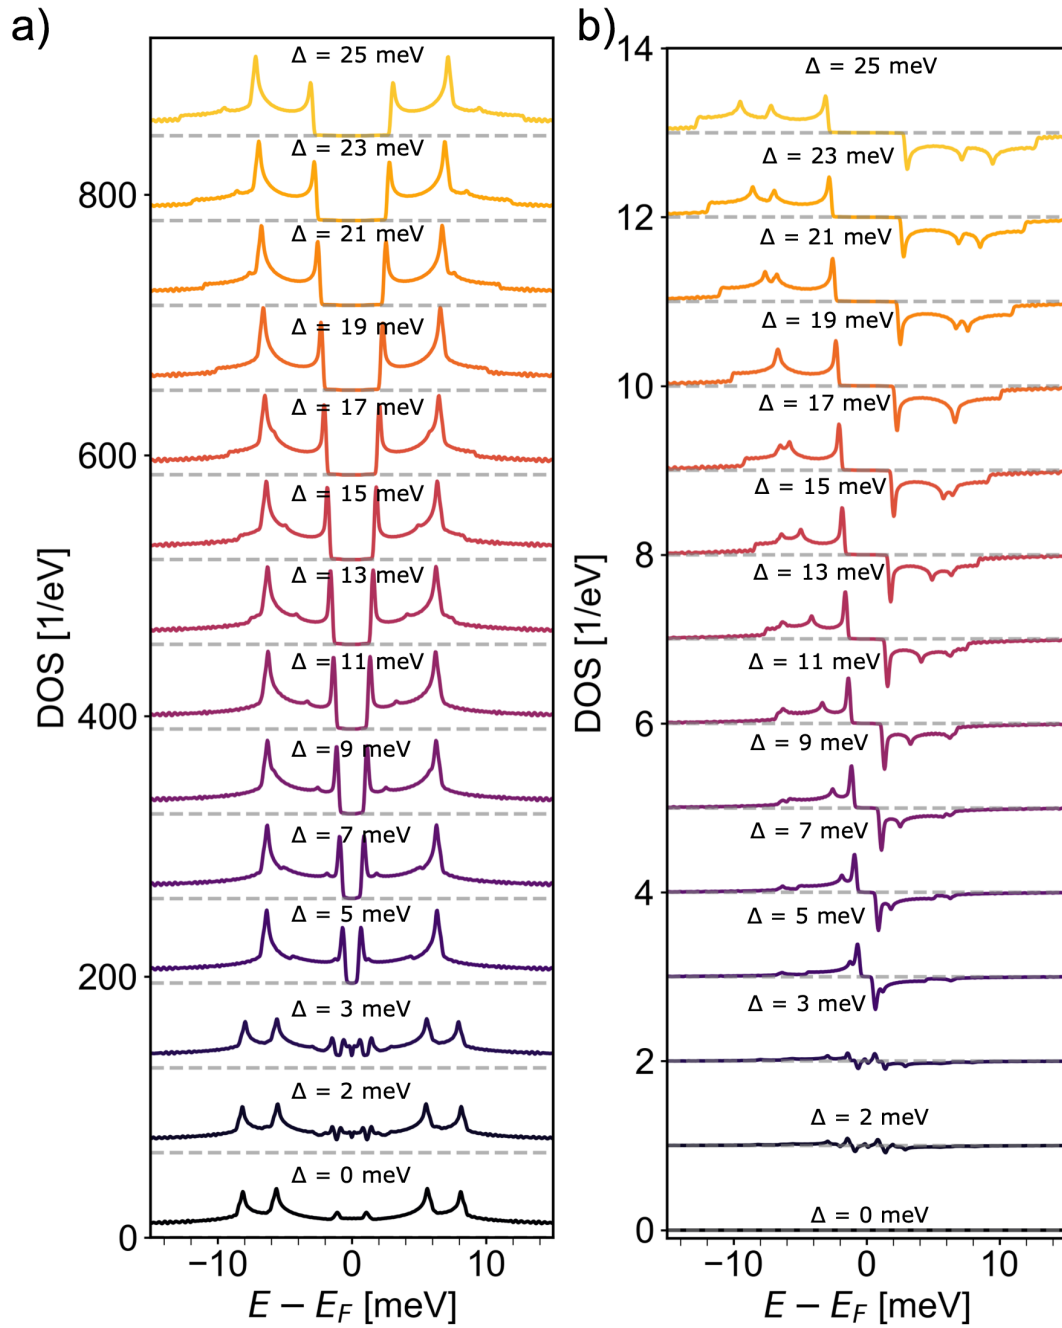

Figure 6: (a) SC-DOS and (b) anomalous DOS (right) for ML FeSe varying the initial value of Δ from 0 to 25 meV. The superconducting pairing potential is initialized only on the Fe atoms.

Figure 7: Superconducting band structure of ML FeSe with $\Delta = 0$ (black), 15 (magenta), or 25 (green) meV. The superconducting pairing potential is initialized only on the Fe atoms.

Figure 8: Superconducting band structure of FeSe/STO with $\Delta = 0$ (black), 10 (magenta), 15 (blue), or 20 (green) meV. The superconducting pairing potential is initialized on the Fe atoms and the oxygen atoms of the TiO_2 terminated surface.

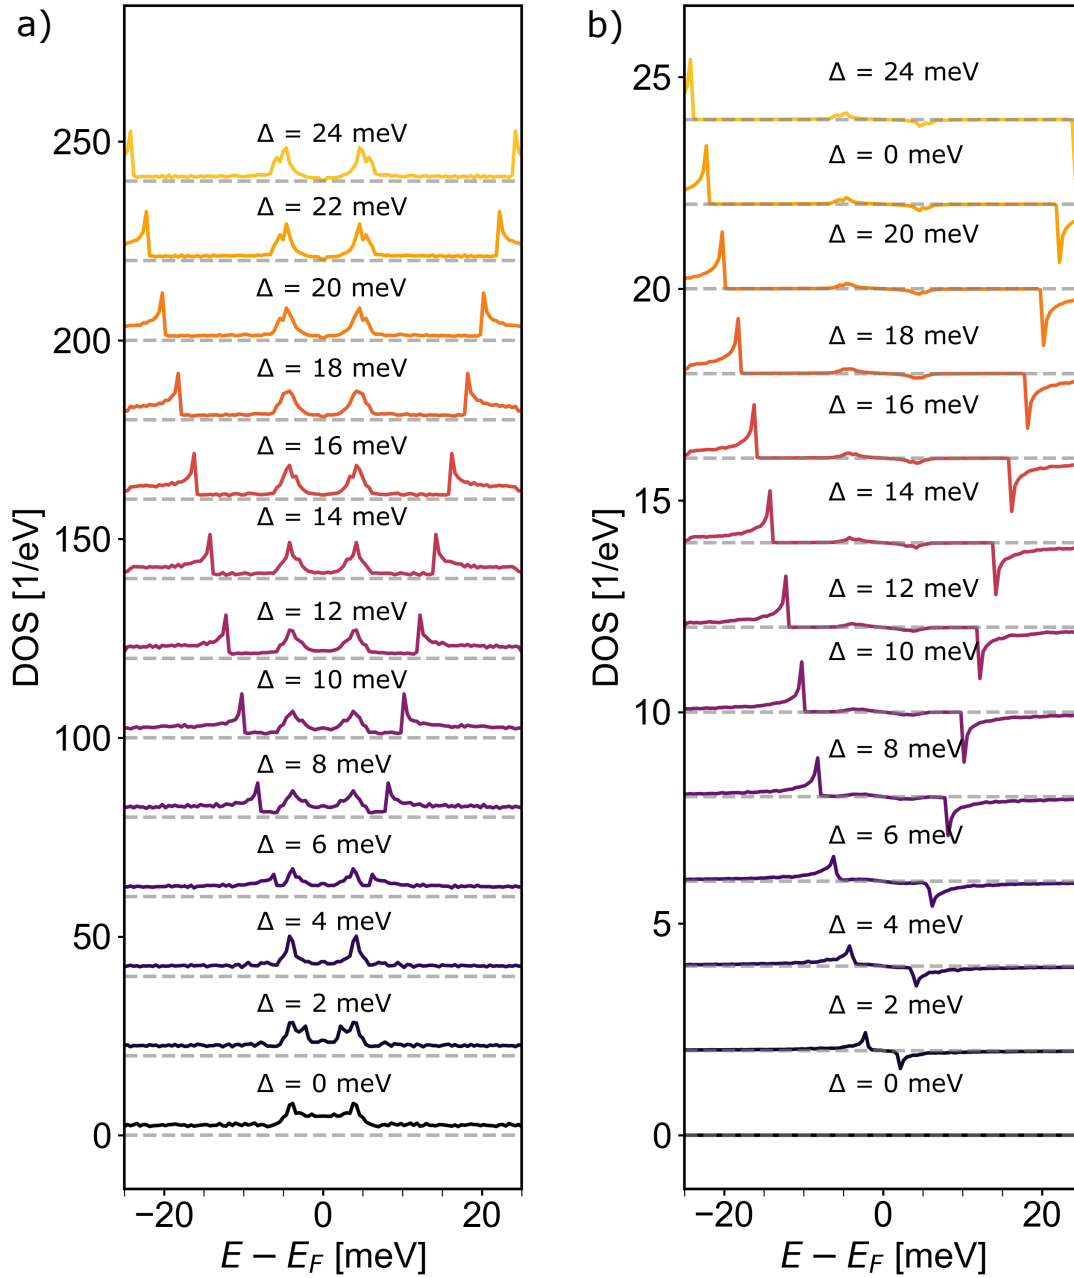

Figure 9: (a) SC-DOS and (b) anomalous DOS (right) for FeSe/STO obtained by varying Δ from 0 meV to 24 meV. The superconducting pairing potential is initialized in the whole unit cell with a constant value.

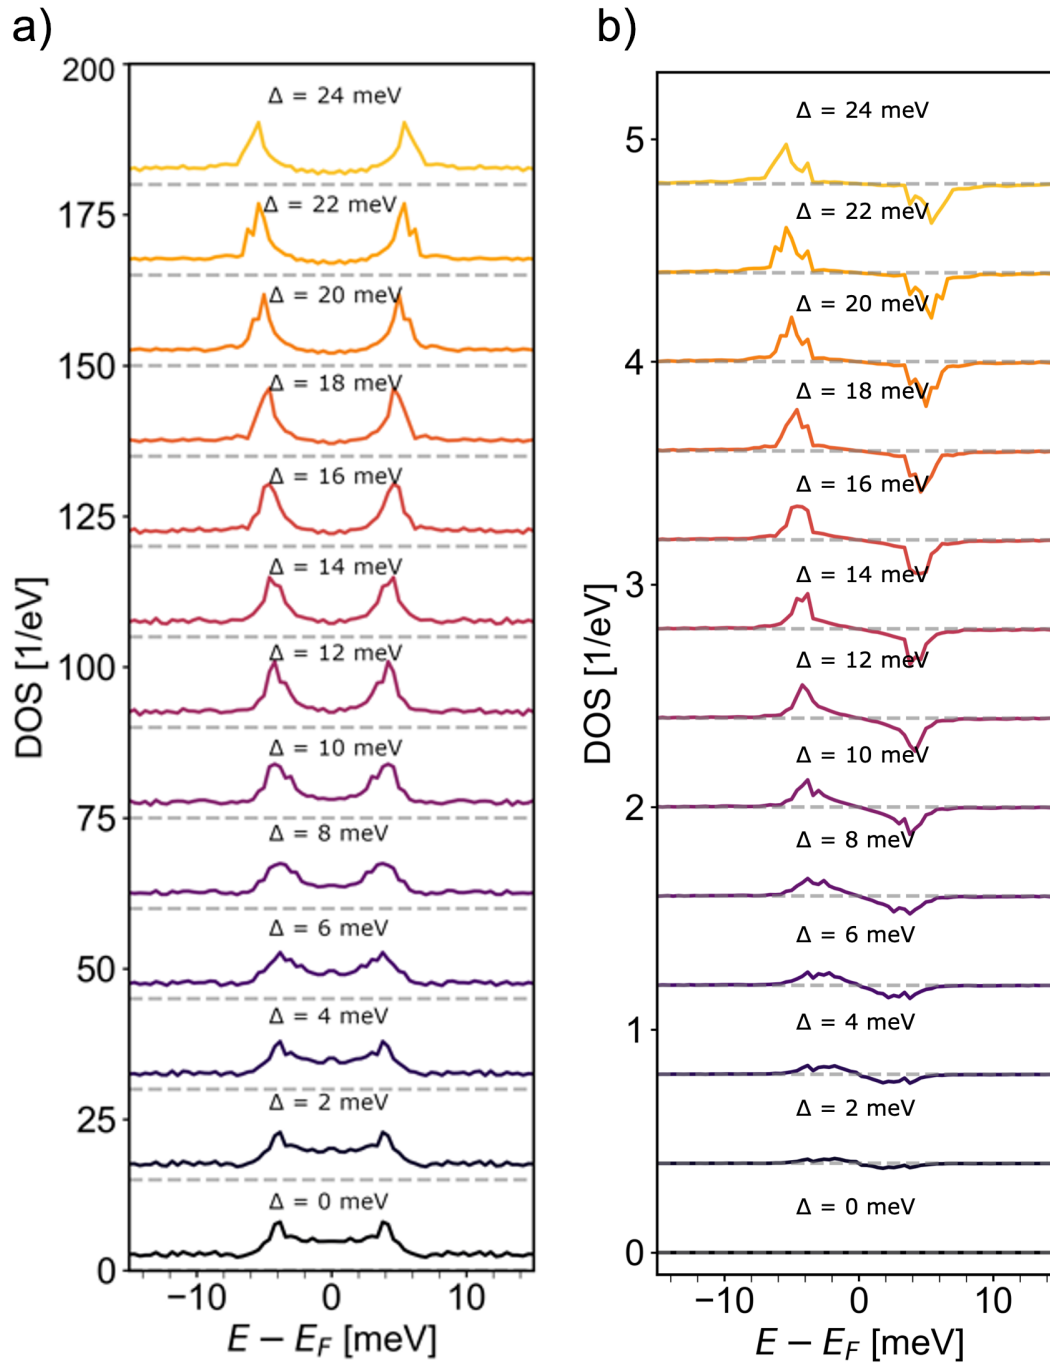

Figure 10: (a) SC-DOS and (b) anomalous DOS (right) for FeSe/STO by obtained by varying Δ from 0 to 24 meV. The superconducting pairing potential is initialized only on the Fe atoms.

Figure 11: (a) SC-DOS and (b) anomalous DOS (right) for FeSe/STO varying Δ from 0 meV to 24 meV. The superconducting pairing potential is initialized only on the Fe atoms and the oxygen atoms of the TiO_2 terminated surface.

Figure 12: (a) SC-DOS and (b) anomalous DOS (right) for FeSe/STO varying Δ from 0 meV to 24 meV. The superconducting pairing potential is initialized only on the Fe atoms and the oxygen atoms of the TiO_2 terminated surface.

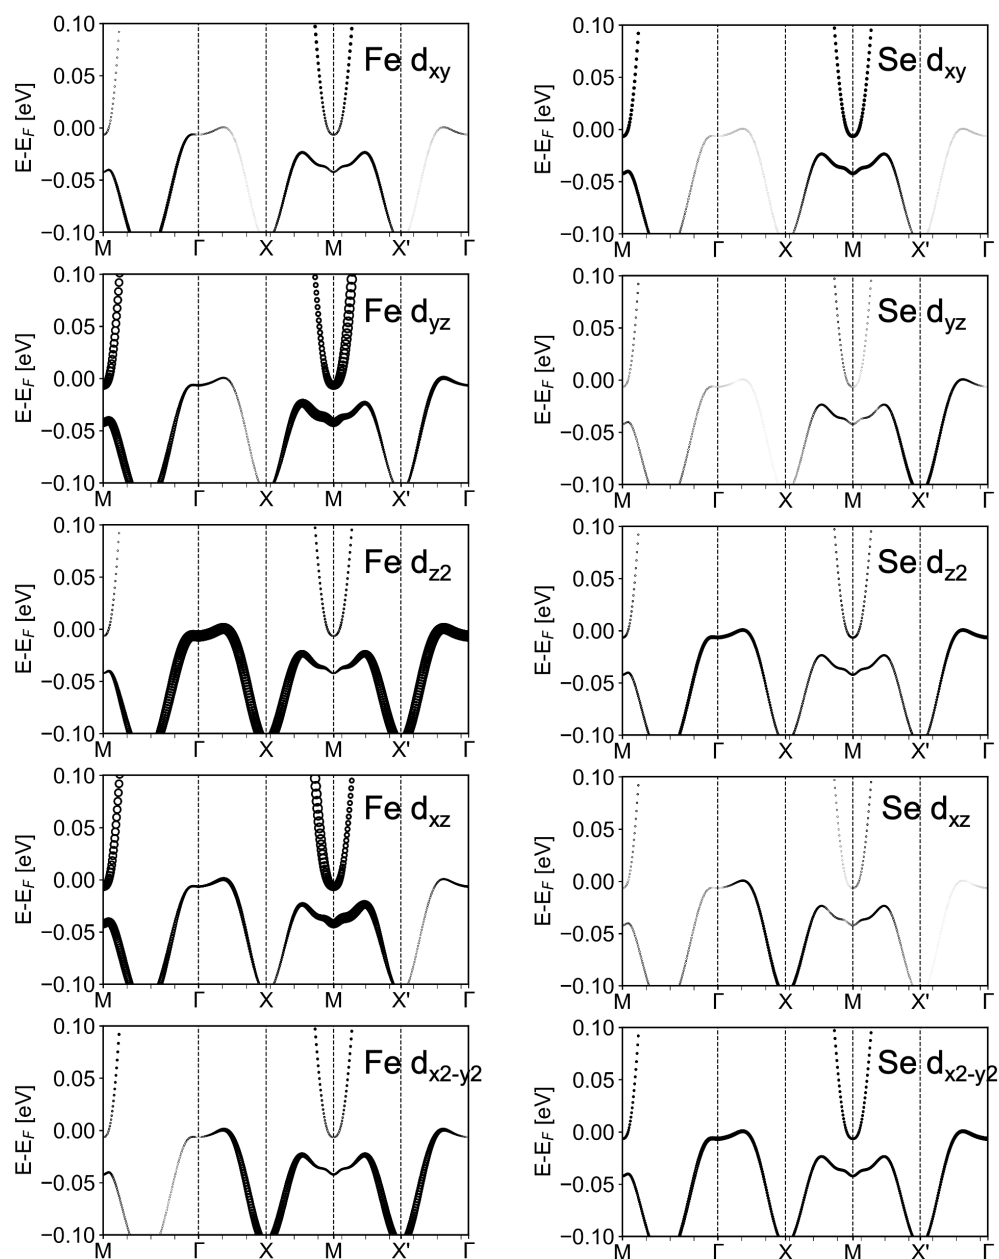

Figure 13: Electronic band structure of ML FeSe, projected on Fe(left) or Se(right) d orbitals.

Figure 14: Convergence of the Hubbard U parameter towards ARPES results: (a) Energy difference between E_F and the last occupied state at Γ , Δ_Γ (b zoom-in) and (c,d) M , Δ_M , as a function of the Hubbard U term.

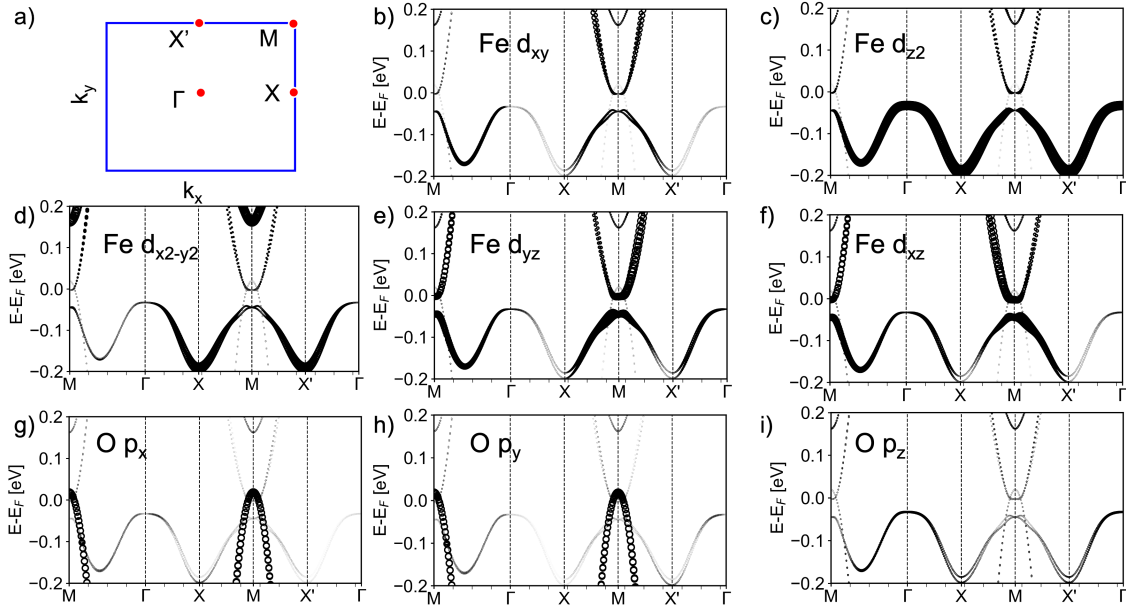

Figure 15: FeSe/STO: Schematic representation of the Brillouin Zone and its high-symmetry points. (a) Normal state electronic band structure projected on (b–f) d orbitals of Fe and (g–i) p -orbitals of O .

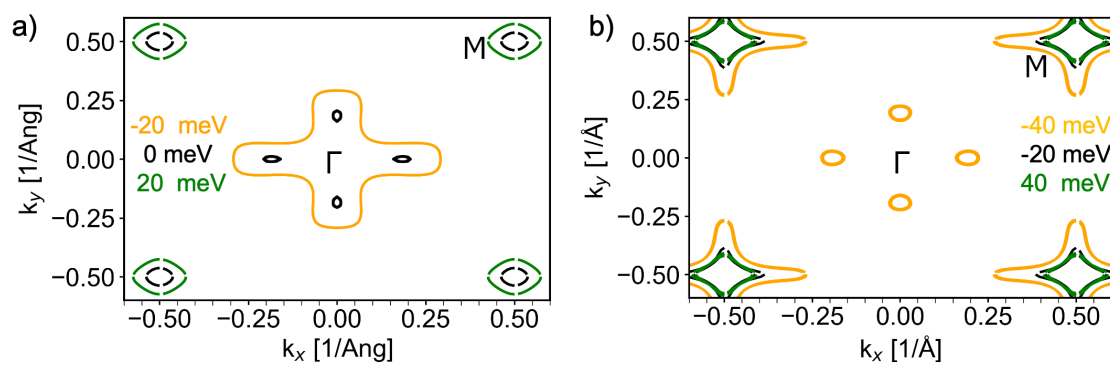

Figure 16: Fermi surfaces of (a) FeSe ML and (b) FeSe/STO in the normal state. The surfaces are shown as constant-energy cuts in the (E, k_x, k_y) frame. Energy values and corresponding colors are indicated in the legend.
